Practical Privacy-Preserving K-means Clustering

Abstract: Clustering is a common technique for data analysis, which aims to partition data into similar groups. When the data comes from different sources, it is highly desirable to maintain the privacy of each database. In this work, we study a popular clustering algorithm (K-means) and adapt it to the privacy-preserving context.

Specifically, to construct our privacy-preserving clustering algorithm, we first propose an efficient batched Euclidean squared distance computation protocol in the amortizing setting, when one needs to compute the distance from the same point to other points. Furthermore, we construct a customized garbled circuit for computing the minimum value among shared values. We believe these new constructions may be of independent interest.

We implement and evaluate our protocols to demonstrate their practicality and show that they are able to train datasets that are much larger and faster than in the previous work. The numerical results also show that the proposed protocol achieve almost the same accuracy compared to a K-means plain-text clustering algorithm.

1 Introduction

Advances in machine learning (ML) have enabled breakthroughs for solving numerous problems across various domains, for example, recommendation services, spam filtering, web search engines, fraud detection, stock market analysis and authentication technologies. Recently, cloud-based machine learning (ML) services provided by major technology companies such as Google, Microsoft, and AWS are getting popular. These services allow modern ML algorithms to be updated and improved via input from their customers. Training models for many such ML algorithms require large-scale data. In practice, the data can be collected from different sources, each of which might belong to a different entity. Internet companies regularly collect large amounts of information from users’ online activities, search engines, and browsing behavior to train more accurate ML models. For example, credit card fraud-detection engines are becoming more accurate by training on large-scale data which combines transaction history, merchant data, and account holder information from financial companies and payment networks. Health data (e.g. genomic, patients) can be used to produce new diagnostic models. Since the data being classified or used for training is often sensitive and may come from different sources, it is imperative to design efficient methods to preserve privacy of data owners.

While recent technologies enable more efficient storage and computation on big data, protecting combined data from different sources remains a big challenge. Recently, privacy-preserving machine learning via secure multiparty computation (MPC) has emerged as an active area of research that allows different entities to train various models on their joint data without revealing any information except the output. In this paper, we study privacy-preserving machine learning techniques for the clustering problem that aims to group similar data together according to some distance measure. Clustering is a popular unsupervised learning method and plays a key role in data management.

Indeed, our clustering setting has many practical applications due to the nature of MPC. For instance, two important and popular applications that motivate our clustering problem are: (1) Customer segmentation where companies can cooperate to cluster their customers into subgroups based on features of the customers. Then, they can run some prediction algorithms for each subgroup, or design dedicated marketing strategy effectively for each subgroup to maximize revenue; (2) Hospitals can cluster their patients into subgroups, then predict behavior of each subgroup, and design special medicine/treatment for each subgroup. In these examples, privacy is of utmost importance.
To this end, we design new and efficient privacy-preserving clustering protocols for an arbitrary partitioning of a dataset. Our major contributions can be summarized as follows:

- First, we introduce an efficient and secure squared Euclidean distance protocol in the amortized sequential setting.
- Second, we build a customized garbled circuit to compute binary secret sharing of the minimum value among a list of secret shared values.
- Furthermore, we present a scalable privacy-preserving clustering algorithm and design a modular approach for multi-party clustering.
- Finally, we implement and evaluate our clustering scheme to demonstrate its scalability. Our scheme is five orders of magnitude faster than the state-of-the-art work [28].

2 Related Work

In this section, we will focus on existing work on privacy-preserving clustering. Earlier work on privacy-preserving clustering has been proposed by Vaidya and Clifton [55], Jagannathan and Wright [27], Jha, Kruger, and McDaniel [29] and Bunn and Ostrovsky [11], Jagannathan and Wright [26]. The work of Vaidya and Clifton [55] addresses privacy-preserving k-means clustering for vertically partitioned database (the database is distributed to different parties in a way that each party holds a subset of the attributes owned by the entity) while the work of McDaniel, and Jagannathan and Wright [26, 29] addresses horizontally partitioned database (each entity is owned by a single participant). The schemes of Jagannathan and Wright [27] and Bunn and Ostrovsky [11] work for arbitrary partitioned database. All of them except [11, 26] reveal intermediate candidate cluster centers, thereby breaching privacy. These protocols can be made more secure but require higher complexity. In [11], Bunn and Ostrovsky present a 2-party privacy-preserving k-means clustering protocol that guarantees full privacy in the semi-honest security model. The protocol hides the intermediate information by calculating the new cluster center using homomorphic encryption. Therefore, the scheme [11] is expensive due to extensive use of homomorphic encryption (HE). In [26], Jagannathan and Wright propose a simple communication-efficient clustering algorithm (called ReCluster) and describe its distributed privacy-preserving version. The privacy-preserving ReCluster does not leak intermediate candidate cluster centers, but reveals the merging pattern in which the adversary could potentially see which two local clusters will be merged in the next iteration.

Recently, the work of Jiawei Yuan and Yifan Tian [60] proposed a practical privacy-preserving K-means clustering scheme that can be efficiently outsourced to cloud servers. They investigated secure integration of MapReduce into their scheme, which makes their scheme extremely suitable for cloud computing environment. However, this work reveals the intermediate closest clustering centers to the server. Many recent works focus on clustering in the outsourcing setting (many parties and a trusted/untrusted mediator) [30, 37, 48, 52], or differential privacy setting [8, 51, 53, 54, 62]. There are few recent works [18, 28, 43, 58] that consider privacy preserving K-means clustering with full privacy guarantees. The solution of [18] only works for horizontally partitioned data. The distributed K-means clustering of [43] is based on Shamir’s secret sharing scheme, thus their scheme requires more than two non-colluding servers. Moreover, it is not clear how to compute the distance metric in this work. The protocols [28, 58] are heavily based on homomorphic encryption and do not scale for large datasets (e.g. more than 10,000 data entries). For example, the state-of-the-art privacy preserving clustering scheme [28] requires almost 1.5 years to cluster a dataset of thousand points. Unfortunately, the paper [58] does not provide running time of their scheme, we only compare the performance of our protocol to that of [28] in Section 7.

Privacy-preserving hierarchical clustering is recently formally studied in [38]. It is well-known that the algorithm for hierarchical clustering has a complexity of $O(n^2 \log(n))$, where $n$ is the number of data points. Today, the most commonly used clustering algorithm is K-means which is greedy and has a complexity of $O(n)$, although it has a disadvantage that we will discuss in Section 7.4.3. Thus, in this work, we focus on privacy-preserving solution for the K-means algorithm.

3 Preliminaries

3.1 Notation

In this work, the computational and statistical security parameters are denoted by $\kappa, \lambda$, respectively. We use $\cdot$ notation to refer to a set. For example, $[m]$ denotes the set $\{1, \ldots, m\}$. Vectors are denoted by bold letters such as $\mathbf{P}$. The $i$-th element of vector $\mathbf{P}$ is $\mathbf{P}[i]$. Define $\mathbb{P}$ and $\mathbb{P}_\oplus$ as the arithmetic and the binary secret sharing of a secret value $\mathbf{P}$, respectively. We de-
note secret sharing $P^A$, $P^B$, where Alice holds $P^A$ and Bob holds $P^B$. Here, the operations $+$ and $\oplus$ are addition and XOR on $\ell$-bit variables, respectively.

### 3.2 Security Model and Computational Setting

There are two classical adversarial models. In the semi-honest (or honest-but-curious) model, the adversary is assumed to follow the protocol, but attempts to obtain extra information from the execution transcript. In the malicious model, the adversary may follow any arbitrary strategy. In this work, we consider the semi-honest model.

We also consider two computational settings:

1. Amortized setting where parties need to evaluate the same function many times on different inputs. For example, a crucial component of K-means clustering algorithm is Euclidean distance computation, which needs to be run repeatedly many times. Indeed, this setting has been formalized and utilized in many previous work such as garbled circuit [21, 35, 57].

2. Sequential setting is similar to the amortized setting where the same function is evaluated many times on different inputs. However, the inputs of the current function evaluation depends on the output from the previous evaluation.

### 3.3 Secret Sharing

According to our privacy requirements, parties should only receive the result (e.g. cluster centers) at the end of the protocol, but all of the values computed in the intermediate steps of the algorithm should be unknown to either party. In our protocol, each computed intermediate value (e.g. a candidate cluster centroid) is shared as two uniformly distributed random values, where each party holds one of these two values such that their sum is the actual intermediate value. Throughout this paper, we use two different sharing schemes: Additive sharing, and Boolean sharing.

To additively share $[x]$ an $\ell$-bit value $x$, the first party chooses $x^A \leftarrow \{0,1\}^\ell$ uniformly at random and sends $x^B = x - x^A \mod 2^\ell$ to the second party. In this paper, we mostly use the additive sharing, and denote it by $[$$]$ for short. For ease of composition we omit the modular operation in the protocol descriptions. To reconstruct an additively shared value $[x]$, one party sends $[x]$ to the party, who reconstructs the secret $x = x^A + x^B \mod 2^\ell$ locally. Arithmetic operations can now be directly applied to these shares. Given two shared arithmetic values $[x]$ and $[y]$, it is easy to non-interactively add the shares by having parties compute $[x+y] = [x] + [y] \mod 2^\ell$.

Boolean sharing can be seen as additive sharing in the field $\mathbb{Z}_2$. The addition operation is replaced by the XOR operation and multiplication is replaced by the AND operation.

### 3.4 Oblivious Transfer

Oblivious Transfer (OT) is a cryptographic primitive for various efficient secure computation protocols. In OT, a sender with two input strings $(x_0, x_1)$ interacts with a receiver who has an input choice bit $b$. An OT protocol allows the receiver to learn $x_b$ without learning anything about $x_{1-b}$, while the sender learns nothing about $b$.

The ideal OT functionality is described in Appendix Figure 7.

One useful variant of OT is Correlated OT (COT) [25], in which the sender’s OT inputs $x_0, x_1$ are chosen randomly subject to $x_0 \oplus x_1 = \Delta$, where $\Delta$ is chosen by the sender. In COT, it is possible to let the protocol itself choose $x_0$ without learning anything about $x_{1-b}$. By doing so, the bandwidth requirement from sender to receiver is reduced by a half, thus the amortized communication cost for an COT is $\kappa + \ell$, where $\ell$ is bit-length of $\Delta$. In our implementation, we require only this weaker OT variant.

### 3.5 Garbled Circuit

Garbled Circuit (GC) is currently the most common generic technique for practical two-party secure computation (2PC). GC was first introduced by Yao [59] and Goldreich et al. [20]. Briefly, the ideal functionality GC is to take the parties’ inputs $x$ and $y$ respectively, and computes $f$ on them without revealing the secret parties’ inputs, which is formalized in Appendix Figure 8.

In our protocol, we use “less than” and “division” GC where inputs are secret shared amongs two parties (e.g. Alice and Bob hold secret shares $[x]$ and $[y]$). To evaluate a function $f$ on shared values, GC first reconstructs the shares, performs $f$ on the top of obtained values, and then secret shares the result $f(x, y)$ to parties. We denote this garbled circuit by $[z] \leftarrow \text{GC}([x], [y], f)$.

### 3.6 Clustering Algorithm

There are several clustering algorithms that have their own pros and cons. Today, the most commonly used algorithm is K-means, which is greedy and computation-
ally efficient. The K-means algorithm consists of two following steps:
(1) Initialize cluster centroids: This step can be implemented using different methods. A very common one is to pick random values for the centroids.
(2) Repeat until convergence (Lloyd’s Iteration):
(a) calculate the distance between each data point and all centroids, assign each data point to the cluster that has the closest centroid.
(b) update the values of the centroids by computing the average of the values of the point attributes that are part of the cluster.
A privacy-preserving K-means clustering is an application of secure computation that allows parties, each holding a set of private data points, to cluster their their combined data sets without revealing anything except for the cluster centers.

4 Our Building Blocks
In this section, we present the enhancements we made to improve secure two-party multiplication and Euclidean distance in the sequential amortized setting, which are the core building blocks in many practical applications. We also introduce a customized garbled circuit to compute the minimum of shared values.

4.1 Secure Arithmetic Multiplication
Assume that Alice and Bob hold secret ℓ-bit numbers x and y respectively, and they want to obtain the arithmetic shared value of the product xy without revealing additional information beyond the output. Secure arithmetic multiplication has been well studied for decades, and can be generated based on either Homomorphic Encryption [17] or OT [19]. Demmler et al. [14] benchmarked the generation of both OT-based and HE-based arithmetic multiplications, and show that with the advantage of recent advances in OT extension, the OT-based protocol is always faster than the HE-based one. Thus, this paper focuses on the OT-based protocol which works as follows: Alice and Bob invoke ℓ instances of OT where Alice acts as an OT receiver and Bob acts as an OT sender. In the i-th OT instance, Bob inputs a pair (m_{i,0}, m_{i,1}) where m_{i,0} ← Z_{2^\ell} and m_{i,1} = (2^\ell y + m_{i,0}) mod 2^\ell; while Alice inputs x[i] as choice bit, where x[i] is the i-th bit of a binary expression x = \sum_{i=0}^{\ell-1} 2^i x[i]. The i-th OT enables Alice to obtain m_{i,x[i]} = (2^\ell x[i] y + m_{i,0}) mod 2^\ell. Finally, Alice can compute the arithmetic shared value z_A by summing up \sum_{i=0}^{\ell-1} m_{i,x[i]} mod 2^\ell. Similarly, Bob computes the arithmetic shared value z_B by summing up \(-\sum_{i=0}^{\ell-1} m_{i,0}\) mod 2^\ell. It is easy to see that z^B = xy – z_A.

4.1.1 Revising Communication-Efficient Secure Multiplication Based on 1-out-of-N OT
With recent improvement to 1-out-of-N OT, [15] proposed to replace 1-out-of-2 OT with 1-out-of-N OT for secure multiplication. In this section, we explicitly revise their 1-out-of-N OT based secure multiplication.
At a high-level idea [15], instead of using binary representation of her secret input x, Alice used an N-base representation, and rewrited x = \sum_{i=0}^{\ell/\log(N) - 1} N^i x[i]; next step is that Alice and Bob invoke \([\ell/\log(N)]\) instances of 1-out-of-N OT to obtain arithmetic shared value of each N^i x[i]y, where Alice has x and Bob has y. Concretely, in the i-th OT where i \in [\ell/\log(N)], Bob acts as an OT sender with input sequence (m_{i,0}, \ldots, m_{i,N-1}) where m_{i,0} ← Z_{2^\ell} and m_{i,j} = (N^j y - m_{i,0}) mod 2^\ell; and Alice acts as an OT receiver with choice value x[i] \in [N]. As output from the 1-out-of-N OT, Alice obtains m_{i,x[i]} = (N^i x[i] y - m_{i,0}) mod 2^\ell. Similar to the original OT-based secure multiplication, Alice computes the arithmetic shared value z_A by setting \sum_{i=0}^{\ell/\log(N) - 1} m_{i,x[i]} mod 2^\ell and Bob set z_B = \sum_{i=0}^{\ell/\log(N) - 1} m_{i,0} mod 2^\ell. The correctness of the protocol follows directly from the fact that z^A + z^B = \sum_{i=0}^{\ell/\log(N) - 1} (N^i x[i] y) mod 2^\ell = xy.

In Appendix A.1, we also discuss an improved communication factor with different choices of N, and the usage of correlated OT for 1-out-of-N OT-based secure multiplication, which reduces the bandwidth requirement by a factor of \frac{x + 1 - (N-1)\ell}{N+M} in comparison with the original 1-out-of-2 OT-based secure multiplication. In particular, Table 6 (in Appendix A.1) shows an 1.11 – 1.51\times lower bandwidth requirement.

4.1.2 Secure Multiplication in the Sequential Amortized Setting
Consider a case where Alice holds a ℓ-bit variable x and Bob sequentially has ℓ-bit variables y_t, \forall t \in [T]. They wish to compute secure multiplication many times to obtain the arithmetic shared value of the product xy, \forall t \in [T]. Instead of repeating the above protocol T times, we propose a simple but efficient solution to compute the multiplication in the sequential amortized setting. By selecting Alice as the OT receiver, we observe that her choice bits x[i] are fixed, where x[i] comes from the expression x = \sum_{i=0}^{\ell/\log(N) - 1} N^i x[i]. Thus, we can reuse OT instances (i.e. reduce T\times number of OT
4.2 Secure Euclidean Squared Distance

Euclidean distance is the "ordinary" straight-line distance between two points, which involves computing the square root of the sum of the squares of the differences between two points in each dimension. In many algorithms (e.g. clustering, texture image retrieval, face-recognition, fingerprint-matching), we only need to compute and compare the distances among the points. Therefore, to improve the computation efficiency, the Euclidean distance can be replaced by the Euclidean squared distance (ESD)\(^1\), which does not affect the output of the algorithms. We denote the ESD between two points \(x\) and \(y\) by \(z \leftarrow \mathcal{F}_{\text{EDist}}(x, y)\).

Consider two points \(P\) and \(\phi\), each has \(d\) dimensions. Assume that both parties have arithmetic secret shared value \([P]\) and \([\phi]\). They want to compute the secure Euclidean squared distance by which both parties obtain the arithmetic shared value of the output

\[\mathcal{F}_{\text{EDist}}(P, \phi).\]

The Euclidean squared distance between points \(P\) and \(\phi\) is given as follows:

\[\mathcal{F}_{\text{EDist}}([P], [\phi]) = \mathcal{F}_{\text{EDist}}(P^A, P^B, \phi^A, \phi^B)\]

\[= \sum_{\rho=1}^{d} (P^A[\rho] + P^B[\rho] - \phi^A[\rho] - \phi^B[\rho])^2\]

\[= \sum_{\rho=1}^{d} (P^A[\rho] - \phi^A[\rho])^2 + \sum_{\rho=1}^{d} (P^B[\rho] - \phi^B[\rho])^2\]

\[+ 2 \sum_{\rho=1}^{d} (P^A[\rho] - \phi^A[\rho])(P^B[\rho] - \phi^B[\rho])\]

Observe that the terms \((P^A[\rho] - \phi^A[\rho])^2\) and \((P^B[\rho] - \phi^B[\rho])^2\) can be computed locally by Alice and Bob, respectively. Since the mixed term \((P^A[\rho] - \phi^A[\rho])(P^B[\rho] - \phi^B[\rho])\) leaks information if known in the clear by a party, it requires to compute this mixed term securely. Clearly, this mixed term can be computed by a secure multiplication on input \(P^A[\rho] - \phi^A[\rho]\) held by Alice and input \(P^B[\rho] - \phi^B[\rho]\) held by Bob.

In data mining applications (e.g. K-nearest Neighbor [12, 31]), parties need to jointly compute the Euclidean distance between each fixed point \(P_i\) and

\(^1\) ESD is not a metric, as it does not satisfy the triangle inequality.
many points $\phi_k$ which are (either sequentially or non-
sequentially) known by parties. For example, Step (2a)
of the K-means clustering algorithm (ref. 3.6) is to
compute the distance between each data point and
all centroids which are updated in Step (2b). Therefore,
the centroids are non-sequentially known by par-
ties in the same iteration but sequentially known be-
tween the iterations. We define the problem of Secure
Euclidean Squared Distance (SESD) as follows: Given
secret shared value of $n$ points $P_i, i \in [n]$, each has
$d$ dimensions, assume that parties must do $T$ itera-
tions, in the $t^{th}$ iteration they compute Secure
Euclidean squared distance between each point $P_i$ and all $K$ points
$\phi_{ik}, k \in [K]$. We describe the ideal functionality for
SESD in Figure 1.

A direct solution [11, 14, 26, 28, 31] uses a secure
multiplication to compute the mixed term $$(P_i^A[p] - \phi_{ik}^A[p])(P_i^B[p] - \phi_{ik}^B[p]), \rho \in [d],$$ for
each Euclidean squared distance $F_{\text{EDist}}(P_i, \phi_{ik}), i \in [n], k \in [K]$. Let $\tau$ be
a number of OT instances used to perform a secure
multiplication. This solution requires $\tau dn KT$ instances
of OTs for all
iterations. We define the problem of Secure
K-means clustering (ref. Section 3.6) needs to find a closest
centroid to each data point. It is needed to hide the
closest centroid. Unlike other secure ML problems (e.g.
K-nearest Neighbor) that can output the secret share of the
centroid/center, secure K-means clustering requires
to output the secret share of the cluster’s index indic-
ing the closest one. We consider the problem that takes the arithmetic secret sharings $[X_1], \ldots, [X_K]$ of
$K$ numbers, and returns binary secret sharings of the
vector $C = (0, \ldots, 1, \ldots)$ (indexed vector), where the ‘1’ appears in the $k^{th}$ coordinate to indicate that
the smallest number is $X_k$. We denote this problem by
$[C]_\oplus \leftarrow F_{\text{min}}^K([X_1], \ldots, [X_K])$.

In previous work [11, 28], $F_{\text{min}}^K$ is implemented
using generic secure computation (e.g. FHE, GC). Using
FHE is still computationally expensive while the GC-
based $F_{\text{min}}^K$ requires $K - 1$ “less than” and $K - 1$ “mul-
tiplexer” circuits to find the minimum value among $K$
input numbers, and $K$ “equality” circuits to determine
the $k^{th}$ coordinate indicating the smallest numbers. We
build a customized garbled circuit to implement $F_{\text{min}}^K$,
which requires only $K - 1$ “less than” garbled circuits
and $(4K - 1)$ instances of OT extension. Note that the
cost of “multiplexer” garbled circuit is $O(\kappa \cdot \ell)$ due to
the need of garbling $\ell$-bit strings [56], while the cost of
OT instances is $O(\kappa + \ell)$.
Figure 3 illustrates the main idea behind our $F_{\min}^K$ protocol. Our protocol can be described in a recursive way as follows. Assume we have secret shared index vector $[C_0]_{\otimes}$ as the output of $F_{\min}([X_1], \ldots, [X_{K/2}])$, we also store the minimum value of minimum value $X_k$ of $X_1, \ldots, X_{K/2}$. Similarly, we have $[C_1]_{\otimes}, [X_k] \leftarrow F_{\min}([X_{K/2}+1], \ldots, [X_K])$, where $X_k$ is minimum value among $X_{K/2+1}, \ldots, X_K$. We observe that index vector $C$ is equal to the concatenation of $bC_0$ and $bC_1$, where $b=1$ indicates that the minimum value is $X_k$, and vice versa. Thus, the parties first evaluate a “less than” gadget circuit on the inputs $X_k$ and $X_{k'}$. We modify the “less than” gadget circuit to output 2-bit binary shares $(\lfloor b \rfloor, \lfloor \overline{b} \rfloor)$. The next step is to efficiently compute the binary secret sharing of $bC_0$.

We rewrite $bC_0 = (bA \oplus bB)(C_0^A \oplus C_0^B)$, and invoke 2 OT instances to output its binary shared values. Concretely, Alice acts as OT sender with a pair input $(m_0 \oplus bC_0^A, m_0 \oplus (bA \oplus 1)C_0^A)$ where $m_0$ is chosen randomly, while Bob acts as OT receiver with a choice bit $bB$. As output from OT, Bob obtains $m_{bB} = m_0 \oplus (bA \oplus bB)C_0^A$. Similarly, Alice acts OT receiver with a choice bit $bA$ and obtains $m'_{bA} = m'_0 \oplus (bA \oplus bB)C_0^B$ while Bob acts as OT sender and knows $m'_0$, Alice sets $z^A = m_0 \oplus m'_{bA}$, Bob sets $z^B = m'_0 \oplus m_{bB}$. It is easy to see that $z^A$ and $z^B$ are binary secret sharing of $(bA \oplus bB)(C_0^A \oplus C_0^B)$.

Recall that we need to store the minimum value of $X_k$ and $X_{k'}$ for further computation. This minimum value is equal to $bX_k + \overline{b}X_{k'}$. To compute shared value of $bX_k = (bA \oplus bB)(X_k^A + X_k^B)$, we again need 2 OT instances, each has a choice bit $bB$ or $bA$. However, since the same OT choice bits are used in this minimum computation and in computing the index vector $C$ above, thus parties can reuse the OT by concatenating the OT sender’s messages. As a result, determining minimum is almost free in terms of computational cost.

Compared to generic GC, this solution adds $\lceil \log(K) \rceil$ rounds, but $K$ is usually small (e.g. $K = 3$ or $K = 15$). Bunn and Ostrovsky [11] proposed a protocol to find a bit output indicating smallest of two numbers by running the secure scalar products many times. With various optimizations to GC over the years, a GC-based minimum protocol is faster than that of [11]. Our protocol is similar to that of Jäschke and Armknecht [28]. However, the protocol [28] requires $K - 1$ “multiplexer” circuits to obtain the minimum value of two numbers, which is mostly free in our protocol. Moreover, [28] uses FHE to compute the shares of index vector $C$ while our protocol costs only four OT instances.

5 K-Means Clustering Framework

In this section, we present our secure K-means clustering protocol and show how to put all building blocks (described in Section 4) together. Recall that the K-means clustering algorithm consists of two steps: Cluster centroids initialization, and Lloyd’s iteration.

5.1 Cluster Initialization

This step can be done using different strategies. A very common one is to pick random values for the of all $K$ groups. This approach can be easily implemented in the privacy-preserving setting by letting one party choose random centroid values, and secret share these values to other party. Another method is to use the values of $K$ different data points as being the centroids, which is also simply implemented in this setting. We now propose another approach specified for privacy-preserving K-means clustering as follows. Each party locally runs the plain-text K-means clustering algorithm to group his/her data point into $[K/2]$ groups. Parties secret share local centroid of each group to each other.

In clustering applications, it is often necessary to normalize input data before running clustering. If the database is horizontally partitioned, each party can locally normalize their data before running our K-means scheme. If vertically partitioned, the party also can locally normalize their data, and do a second normalization based on agreed global parameters.

5.2 Lloyd’s Iteration

Lloyd’s iteration can be divided into four steps:
(1) Calculate the distance between each data point and cluster centers using the Euclidean squared distance
(2) Assign each data point to the closest cluster center
(3) Recalculate the new cluster center by taking the average of the points assigned to that cluster.
(4) Repeat steps 1, 2 and 3 iteratively either a given number of times, or until clusters can no longer change.

We notice that the data points are fixed during the training while the cluster centers can be changed between two iterations. Thus, our SESD protocol can be directly applied to Step (1) of Lloyd’s iteration.

5.2.1 Approximation of Euclidean Distance

In Machine Learning, Euclidean distance (norm-2) is the most common distance measure used in K-means clustering. However, its main drawback is the high computational cost due to the multiplication operator.
Thus, Manhattan metric (norm-1) and Chessboard metric (norm-∞) are often considered as alternatives. The Manhattan distance between two points \( x \) and \( y \) is the sum of the absolute differences of their coordinates (e.g., \( \sum_{i=1}^{d} |x_i - y_i| \)). The Chessboard distance between two points is the greatest of their absolute differences along any coordinate dimension (i.e., \( \max_{i \in [d]} |x_i - y_i| \)). We denote the Manhattan and Chessboard distance between \( x \) and \( y \) by \( z \leftarrow F_{\text{MDist}}(x, y) \), \( z \leftarrow F_{\text{EDist}}(x, y) \), respectively.

We implement secure Manhattan and Chessboard distance, and report their runtime in Section 7.3. We calculate the absolute differences of two values, and find the greatest of these differences using a garbled circuit.

5.2.2 Assigning Data Point to Clusters

From Step (1), parties have arithmetic secret shared value \([X_{i,k}]\) of the distance from each point \( P_i, i \in [n] \), to the cluster center \( \phi_k, k \in [K] \). For each data point \( P_i \), we find its nearest cluster by invoking our \( F_{\text{min}} \) protocol (as described in Section 4.3). The index vector output \([C_i]_\oplus \leftarrow F_{\text{min}}([X_{1,1}], \ldots, [X_{i,k}])\) indicates which cluster center this data point is assigned to.

5.2.3 Updating Cluster Centers

We form a matrix \( C \) of size \( n \times K \), where each row is index vector \( C_i \) obtained from Step (2). Let \( M_k, k \in [K] \), be the row of the matrix transposition of \( C \) (see Figure 9 in Appendix B). It is easy to see that the \( i^{th} \) element of \( M_k \) is set to be 1 if and only if the data point \( P_i \) is assigned to the cluster \( k \). Therefore, we can calculate the new centroid by taking the mean:

\[
\varphi_k = \frac{\sum_{i=1}^{n} M_k[i] P_i}{\sum_{i=1}^{n} M_k[i]} = \frac{\sum_{i=1}^{n} (M_k^A[i] \oplus M_k^B[i])(P_i^A + P_i^B)}{\sum_{i=1}^{n} (M_k^A[i] \oplus M_k^B[i])}
\]

To compute the secret sharing of the updated cluster \( \varphi_k \), parties first compute the numerator and denominator and then calculate the reminder using a division garbled circuit. Similar trick used in determining minimum of two shared numbers in Section 4.3, the numerator can be implemented using \( 4n \) OT invocations. Since the same bits \( M_k^A[i] \) and \( M_k^B[i] \) are used in both numerator and denominator computation, we can reuse the OT instances to computing the denominator. Therefore, updating the centroid \( \varphi_k \) requires \( 4n \) OT instances and one division garbled circuit.

5.2.4 Checking the Stopping Criterion

After obtaining the secret sharing \([e_k]\) of the Euclidean squared distance between the new cluster centroid \( \varphi_k \) and \( \phi_k \), parties locally sum up these shares and invoke a ‘min’ garbled circuit \( GC(\sum_{k=1}^{K} [e_k], \epsilon, min) = 1 \) to check the stopping criterion.

5.3 Main Construction

We describe the main construction of K-means clustering protocol in Figure 4. It closely follows and formalizes these above steps presented in sections 5.1 and 5.2. Note that the input/output of each Lloyd’s steps are secret shares of corresponding variables.

Theorem 1. The protocol in Figure 4 securely computes the K-means clustering in semi-honest setting, given the ideal Oblivious Transfer (OT), Euclidean Squared Distance (SESD), and Garbled Circuit (GC) primitives defined Figure 7, Figure 1, and Section 3.5, respectively.

Proof. We exhibit a simulator \( Sim \) for simulating a corrupt party Alice. The simulator for Bob should be the same.

\( Sim \) simulates the view of corrupt Alice, which consists of her input/output and received messages. \( Sim \) proceeds as follows. It calls \( F_{\text{EDist}} \) simulator \( Sim_{F_{\text{EDist}}}([P_i], [\phi_k]), \forall i \in [n], k \in [K] \), and then simulates step (II.b) by calling \( Sim_{F_{\text{min}}}([X_{i,1}], \ldots, [X_{i,K}]), \forall i \in [n] \), and appends its output to the general view. For step (II.c), \( Sim \) first computes the numerator/denominator using OT, runs simulator \( GC \), and appends its output to the view. We now argue the indistinguishability of the produced transcript from the real execution. For this, we formally show the simulation by proceeding the sequence of hybrid transcripts \( T_0, \ldots, T_4 \), where \( T_0 \) is real view of \( C \), and \( T_4 \) is the output of \( Sim \).

**Hybrid 1.** Let \( T_1 \) be the same as \( T_0 \), except the \( F_{\text{EDist}} \) execution is replaced with running the simulator \( Sim_{F_{\text{EDist}}}([P_i], [\phi_k]), \forall i \in [n], k \in [K] \). Because \( Sim_{F_{\text{EDist}}} \) is guaranteed to produce output indistinguishable from real, \( T_0 \) and \( T_1 \) are indistinguishable.

**Hybrid 2.** Let \( T_2 \) be the same as \( T_1 \), except the \( F_{\text{min}} \) execution is replaced with running the simulator \( Sim_{F_{\text{min}}}([X_{i,1}], \ldots, [X_{i,K}]), F_{\text{min}}^{k_{\text{min}}} \) takes the secret share value of the Euclidean squared distance between point \( P_i \) and cluster \( \phi_k \), which does not reveal any information (e.g. the distance). Moreover, the output of \( Sim_{F_{\text{min}}} \) is indistinguishable from real execution, thus \( T_2 \) and \( T_1 \) are indistinguishable.

**Hybrid 3.** Let \( T_3 \) be the same as \( T_2 \), except the execution step (II.b) is replaced as follows.
Fig. 4. Our Privacy-preserving K-Means Clustering Framework.

6 Multi-party Clustering

In this section, we extend our two-party clustering scheme to support a set of users $U_0, \ldots, U_m$ who want to train a clustering model on their joint data. We consider two following models:

1. **Server-aided model**: Given a set of users with private datasets, server-aided model allows the clients to outsource the computation to two untrusted but non-colluding servers.

2. **Multi-party computation**: users jointly train the model on their joint data without requiring a trusted/untrusted additional party.
6.1 Server-aided Model

The server-aided setting has been formalized, utilized in various previous work [32], and in privacy-preserving machine learning model [40, 41]. Given a semi-honest adversary $A$ who can corrupt any subset of the users and at most one of the two untrusted servers, the security definition of this model requires that such an adversary only learns the data of the corrupted users and the final model, but nothing else about the remaining honest non-corrupted users’ data. It is easy to see that our K-means clustering scheme (described in Section 5) can be directly applied to this model where users can secret share their inputs among the two untrusted servers. This distribution step can be done in a setup phase. Therefore, the advantage of this model is that it does not require the users to be involved throughout the protocol computation.

6.2 Multi-party Computation Model

The data stream model has attracted attention in machine learning and data analysis, and is used to analyze very large datasets. Popular clustering data stream algorithms are CURE [23], BIRCH [63], and STREAM [22] which achieves a constant factor approximation algorithm for the k-Median problem. A clustering data stream is a divide-and-conquer algorithm that divides the whole data into small pieces, and clusters each one of them using K-means, then clusters the resulting centers. Inspired by this technique, we propose a secure clustering scheme in multi-party setting. This model provides a weaker security guarantee where we assume that we know user $U_0$ who does not collude with other users.

A solution is to perform a secure two-party computation where each user plays the role of one party in our privacy-preserving clustering scheme (ref. Section 5). Concretely, two users $U_0$ and $U_i, i \neq 0$, perform 2-party secure K-means clustering. As a result, users receive the shared value of the cluster centroids (denote them as $\phi_k^{U_0}$ and $\phi_k^{U_i}$). Next step is that user $U_i$ sends these obtained shared values $\phi_k^{U_i}$ to user $U_{i+1}$ in the clear (this captures the property that users $U_{i}, i \neq 0$, are not colluding with $U_0$, therefore, cannot reconstruct the intermediate cluster centroids). Users $U_0$ and $U_{i+1}$ now can use the values $\phi_k^{U_0}$ and $\phi_k^{U_i}$ as the initial centroids for training model on their data.

7 Experimental Results

We implement a privacy-preserving clustering system based on our proposed protocols and report the experimental results in this section. We also compare the performance of our scheme with the state-of-the-art privacy-preserving clustering protocols in [53] and [28].

7.1 Experimental Setup

To understand the scalability of our protocol, we evaluate it on a single server which has 2x 36-core Intel Xeon 2.30GHz CPU and 256GB of RAM. Although there are many cores, each party does their computation only on a single thread. We run all parties in the same network, but simulate a network connection using the Linux tc command: a LAN setting with 0.02ms round-trip latency, 10 Gbps network bandwidth. We observe that running times on WAN can be computed with the linear cost model as the overall running time is equal to the sum of computation time and data transfer time. Moreover, the previous work has conducted experimental numbers in LAN setting only. Thus, we will focus on the LAN setting in all the experiments below.

For the most direct comparison to the work of Jäschke and Armknecht [28], we matched the test system’s computational performance to that of [28]. We evaluate our protocol on a machine Intel Core i7 2.60GHz with 12GB RAM.

In our protocol, the base-OT is implemented using Naor-Pinkas construction. The system is implemented in C++, and builds on use the primitives provided by Ivory Runtime library [4] for garbled circuits (free XOR [36], half-gate [61], fixed-key AES garbling optimizations [9]), and libOTe [49] for OT extension of [25]. All evaluations were performed with statistical security parameter $\lambda = 40$ and computational security parameter $\kappa = 128$. Our complete implementation is available on GitHub: https://github.com/osu-crypto/secure-kmean-clustering.

7.2 Datasets

For fair comparison, we use two datasets, each of which was evaluated in some relevant previous works:

<table>

</tr>
</tbody>
</table>

Table 1. Descriptions of the Datasets, where $n$, $K$, $T$ is the size of database, number of clusters, and number of iterations, respectively.
• The first dataset is Lsun dataset [5], which consists of 400 data points of 2 dimensions and 3 clusters. This dataset was evaluated in [28].
• The second dataset is a 2D synthetic dataset S1 [16], which was experimented in [53] in the Differentially Privacy setting. The S1 dataset contains 5,000 data points and 15 Gaussian clusters.

We consider arff [2] dataset for a visual accuracy comparison. The dataset consists of 1000 data points of 4 clusters and 2 dimensions. Furthermore, to verify the performance of our scheme for datasets with different dimensions, we extract scikit-learn [44] to get dataset that contains 10000 vectors in \( d \in \{2,4,6,8,10\} \) dimensional spaces, and group the dataset into 9 clusters. Finally, we generate synthetic 2D datasets with sizes of \( (10000,100000) \) and \( K \in \{2,5\} \). Table 1 summarizes the datasets used in our experiments.

7.3 Experiments for Distance Metric

We start with the experimental results for the secure Euclidean squared distance protocol (its functionality described in Figure 1), and compare it with previous privacy preserving solutions [14, 31].

7.3.1 Secure Euclidean Squared Distance

To examine how our SESD protocol scales, we run experiments on datasets with \( n \in \{2^{12},2^{16}\} \) size, \( K \in \{4,8,16\} \) clusters, and \( T \in \{10,20\} \) iterations. The field size is set to \( \ell = 2^{32} \) and the dimensions of the data is fixed to be \( d = 2 \). We note that \( \ell \) and \( d \) do not affect the comparison with previous works.

Table 2 shows the running time (in millisecond) to perform a SESD, and the number of OT instances needed. Recall that SESD from the \( i^{th} \) point to the \( k^{th} \) cluster is equal to

\[
F_{\text{EDist}}([P_i],[\phi_k]) = \sum_{\rho=1}^{d} (P_i^A[\rho] - \phi_k^A[\rho])^2 + \sum_{\rho=1}^{d} (P_i^B[\rho] - \phi_k^B[\rho])^2 + 2 \sum_{\rho=1}^{d} (P_i^A[\rho] - \phi_k^A[\rho]) (P_i^B[\rho] - \phi_k^B[\rho])
\]

All previous privacy preserving clustering protocols [11, 26, 28] use a standard secure multiplication (based on garbled circuit or homomorphic encryption) to compute the mixed term of the above equation. Recently, [31] proposed and implemented SESD using the state-of-the-art secure multiplication [14]. The baseline in Figure 1 shows the performance of [31]. We obtain the baseline measurements by running the implementation of ABY [3, 31]. We note that in the baseline the running time per SESD does not depend on \( n, K, T \) since this solution computes the mixed term independently from other SESD instances. Therefore, this solution requires \( \ell d n K T \) instances of OTs in total. For a database of size \( n = 2^{16} \), \( K = 16 \), and \( T = 20 \), this baseline requires around \( 2^{30} \) OT instances, which does not scale well.

The mixed term can be written as the formula (2). We observe that in each \( i^{th} \) iteration, parties perform \( K \) secure multiplications with the same factor \( P_i^A \) or \( P_i^B \), thus, we compute our new SESD formula (2) by using the technique of [39]. Concretely, all OT sender messages can be concatenated before encrypting and sending them to other party. The column “Our Amortized” in Table 2 and Table 7 (in Appendix) present the performance of this optimization. For \( n = 2^{16}, K = 4 \), and \( T = 20 \), we obtain an overall running time of 0.172 ms per SESD in the amortized setting. Increasing the number of clusters from 4 to 16, our protocol shows a factor of 3.44× improvement in terms of running time, due to the fact that it amortizes well. This solution requires \( \ell d (2n + K) T \) instances of OTs in total. Note that the technique of [39] cannot be directly applied to compute SESD without breaking down \( F_{\text{EDist}}([P_i],[\phi]) \) into our formula (2). In other words, the technique of [39] is worthless if computing the mixed term directly. Therefore, we do not consider [39] as the baseline for SESD comparison.

In the K-means application, the centroids are changing after each iteration, thus our final secure multiplication protocol allows these values to change during the execution. The column “Sequential Amortized” shows its performance (described in Section 4.2), where parties can reused OT instances across all iterations. Our experiments show that our SESD is highly scalable. For a database of size \( n = 2^{16} \), \( K = 16 \), and \( T = 20 \), our protocol requires around \( 2^{23} \) OT instances, which is 159× lower than that of the baseline. In terms of running time, our protocol requires only 0.135 ms to compute a SESD in the sequential amortized setting with \( n = 2^{16}, K = 4 \), and \( T = 10 \). For the same \( n \), when increasing the number of cluster to \( K = 16 \), and the number of iteration to \( T = 20 \), our protocol running time is 0.03 ms per SESD.

Of particular interest is the column “Improved Factor”, which presents the ratio between the runtime and the number OT required of the baseline and our scheme. Our protocol yields a better speedup when the dataset size and number of iterations are larger. For smallest dataset size of \( n = 2^{12}, K = 4 \) and \( T = 10 \), the protocol achieves a speed up of about 47×. When considering the larger database size \( n = 2^{16}, K = 16 \), the speed up of...
It is easy to see from Table 3, our amortized SESD cost is \(8.9 \times - 38.5 \times\) faster than the cost of computing a Manhattan distance, and \(10.5 \times - 40.5 \times\) faster than that of Chessboard distance. We note that our SESD is amortized well in both sequential and non-sequential setting. When executing more and more SESD (between one fix point and other points), the cost drops dramatically to few microseconds per SESD. Thus, we use SESD in our experiments for privacy-preserving clustering.

Very recently, [12] proposed an efficient SESD protocol based on additive homomorphic encryption, which is used for k-Nearest neighbor search problem. However, it is not quite clear how to extend their protocol to compute a large number of SESD in our sequential amortized setting. From [12, Table 1], their protocol takes 19.8 seconds to compute one million distances between two points, each point has 128 dimensions. Thus, one multiplication of two 8-bit integers [12] requires about 1.54 nanoseconds in the average cost. On the other hand, from Table 3, our SESD takes only 0.011 nanoseconds to compute one multiplication of two 32-bit integers in the sequential amortized cost.

### 7.4 Experiments for Clustering

In this section we present our experimental results of our privacy-preserving clustering protocol. We ran our experiments on a large number of synthetic data sets to show the practicality and scalability. We also benchmark our scheme on the real dataset for comparison with previous work.

The offline phase includes the base OTs. We generate garbled circuits and OT extensions needed for \(F_{mult}^K\), executed in the online phase (even these steps can be performed in the offline phase).

#### 7.4.1 Scalability

**7.4.1.1 Experiments with Generated Dataset**

We generate 2-dimensional synthetic data sets on the range of set sizes \(n \in \{10000, 100000\}\). Our synthetic data set generator takes a number of cluster \(K \in \{2, 5\}\). There exist various criteria to stop iterations in K-means. In this experiment, we simply set the number of iterations to a fixed value (say, \(T \in \{10, 20\}\)).

We report both the running time and the communication cost of our scheme in Table 4. We recall that our scheme consists of three major phases, which are distance phase, assignment phase, and update phase (as described in Figure 4). To understand the performance of each phase, we also report their empirical results in Table 4. The main cost of our scheme comes from the

### Table 2. Running time in millisecond per SESD (described in Figure 1), where \(n, K, T\) is the size of database, number of clusters, and number of iterations, respectively, dimension \(d = 2\), and bit-length \(\ell = 32\).

134.1 \(\times\) is obtained for \(T = 10\) and 148.1 \(\times\) at \(T = 20\) iterations.
second phase, where we need to evaluate \((n - 1)\) “less than” garble circuits. To save time in evaluating this phase a case of \(n = 10^5\) and \(K = 5\), instead of running it in every iteration, we measure its runtime for one round iteration, and multiply by the number of iterations \(T\). As shown in Table 4, our scheme is practical. Small-size problems are few minutes; and larger size problems \((n = 100,000)\) is under 2 hours, all single-threaded. In particular, it only takes 1.92 minutes to train a clustering model securely on 10,000 data samples with 2 clusters. From 1.92 minutes needed for privacy preserving training, only a small portion is spent on the distance and update phases. Our scheme is mostly based on symmetric-key operations, it introduces a overhead on the communication, namely 2.5GB for \(n = 10,000\). When \(n = 100,000\) and \(K = 5\), our protocol takes 115.78 minutes to train the model, in which 81.5\% of the total runtime comes from the assignment phase.

It is worth noting that our protocol is amenable to parallelization. Specifically, the computing SESD and updating the centroids steps can be parallelized. Moreover, one can compute \(F^K_{\min}\) in parallel per branch of the tree (see Figure 3). Therefore, we expect that our protocol can securely cluster a large dataset of \(n = 100,000\) under 5 minutes using 32 threads. In addition, we estimate that our scheme can deal with datasets of millions points by using several servers (e.g. 10 servers).

### 7.4.1.2 Experiments with Different Dimensions

From the breakdown performance of our scheme in Table 4, we can observe that the majority (70-80\%) of the total cost is for the “Assign Points to Cluster” step, which is independent of the dimension because distance metric is a number. Additionally, from Table 2, it can be seen that the cost of computing SESD increases \(5\times\) as the dimension increases from 2 to 10, which implies that the running time of SESD is almost linear in the dimension.

To understand the impact of different dimensions on the total cost of our scheme, we evaluate our protocol using scikit-learn [44] with different values of \(d\) \(\in\{2, 4, 6, 8, 10\}\). The number of iterations \(T\) is set to be 15. The numerical results are reported in Figure 5. It can be observed that increasing \(d\) affects only the SESD and “Centroid Update” phases in the clustering algorithm. For smaller \(d\), these two phases account for only a small portion of total running-time of our scheme. When increasing dimension to 10, these phases takes 30\% of the total cost.

### 7.4.2 Comparison with Prior Work

We compare our prototype to the state-of-art privacy-preserving clustering protocols of Jäschke and Armknecht [28], and differential privacy clustering protocols of Su et al. [53]. Since implementation of the work [28] is not publicly available, we use their reported experimental numbers.

#### 7.4.2.1 Comparison with [28]

For the most direct comparison, we perform a comparison on the Lsun dataset [5] to match the dataset used in [28], Table 2. We also matched the test system’s computational performance to that of [28]. Since [28] ran experiments on Intel i7-3770, 3.4 GHz, 20GB RAM; we use a similar (1.32× slower) machine as reported in Section 7.1. Table 5 presents the running time of our protocol compared with [28]. The work of [28] evaluate three different versions of privacy-preserving K-means clustering algorithm.

The first scheme [28] is exact K-means algorithm, in which the authors use TFHE library [6] to implement ciphertext division \(c_1/c_2\), where both \(c_1\) and \(c_2\) are ciphertexts. This is a needed operation in the update phase which recalculates the new cluster center by taking the average of the values of the point’s attributes that are part of the cluster. The authors encoded each data entry with 35 bits, in which 20 bits are used for the numbers after the decimal point. In our experiment, we use 32 bits to encode the data entry and use garble circuits to implement the ciphertext division operation. We fix the number of iterations to be \(T = 15\) rounds, which is the same as in the experiment in [28]. As shown in Table 5, the protocol [28] costs 545.91 days to train Lsun dataset.
While our scheme requires only 22.21 seconds (i.e., five orders of magnitude faster than [28]).

Since the main computational cost of their exact version comes from the division operation where both numerator and denominator are ciphertext, the authors modify the update phase of K-means algorithm to have denominator to be a constant number. Concretely, their new $k^{th}$ cluster center can be computed by $\frac{\sum_{i=1}^{n} P'_i}{n}$, where $P'_i$ is exactly the data entry $P_i$ if this data entry is assigned to the $k^{th}$ centroid, otherwise, $P'_i$ is equal to the old centroid value $P_k$. They call this algorithm the stabilized K-means. Since the centroids move more slowly in this scheme, the experiment [28] chooses $T = 40$ iterations which is also used in our experiment. Section 7.4.3 shows that our update phase takes only a small portion of the total runtime, therefore, we do not apply the stabilized technique [28] in our protocol (which is in favor of [28]). From Table 5, the protocol [28] costs 15.56 hours to train Lsun dataset while our scheme requires 48.9 seconds, an approximate $1145\times$ improvement.

The third scheme [28] is approximate K-means algorithm, where Euclidean distance is replaced by Manhattan distance. This modification speeds up the runtime of the protocol [28]. However, as discussed in Section 5.2.1, the amortized cost of our SESD is much better than that of Manhattan, thus we use SESD in our experiment. We fix the number of iterations to be $T = 40$ rounds, which is also used in the experiment [28]. Our experimental results show that our clustering scheme is $1138\times$ faster than the third version of privacy-preserving K-means clustering algorithm [28].

### 7.4.2.2 Comparison with [54]

We do not intend to give a detailed comparison between MPC-based and DP-based methods because the settings and design goals are different (comparing apples and oranges). We only briefly compare running time of these two methods in Table 5 to examine the performance gap between our semi-honest scheme and DP security model. The experimental results on 2D synthetic dataset S1 [16] show that our privacy-preserving K-means clustering scheme is only $63.5\times$ slower than the differential privacy model [54]. We include more discussion in Appendix A.3.

### 7.4.3 Accuracy

The accuracy is the percentage of entities in the evaluation set grouped correctly. In this section, we compare the accuracy of the produced models using our proposed approach and the plain-text K-means clustering algorithm (i.e., without privacy). For a visual comparison, we use the 2D dataset from arff [2] and S1 [16], which have the actual labels or ground truth centroids shown in Appendix B (Figure 10a and Figure 11a, respectively). We evaluate the plain-text algorithm and our privacy-preserving scheme, and present the obtained groups centroids in Appendix B (Figure 10b, 11b, 11c).

All functions employed in our framework is the same as the original functions used the plain-text K-means clustering, except the update phase (step 3c in Figure 4), where we truncate the fractional part of the new cluster centroid to obtain an integer. Note that we use the truncation technique mentioned in [39]. The experimental results show that the truncation has a negligi-

ble impact on model accuracy compared to the original function. Our scheme with truncation reaches the same accuracy compared to a plain-text $K$-means clustering on decimal numbers. When training dataset arff using both our privacy preserving approach and plain-text $K$-mean algorithm, 95% of entities have been grouped correctly compared to the ground truth model.

Indeed, the $K$-means algorithm itself already has certain errors. A well-known disadvantage of the $K$-means algorithm is that its performance lacks of consistency. A random choice of cluster centers at the initialization step may result in different clusters since the algorithm can be stuck in a local optimum and may not converge to the global optimum. Therefore, in practice, we often run the algorithm with different initializations of centroids, and then pick the result of the run that yields the lowest sum of squared distance. Hence, we also compare our privacy-preserving model to the plaintext $k$-mean algorithm on S1.

Given the ground-truth of dataset S1, we find the best matching from each obtained centroid to them. We calculate the Euclidean distance between each obtained centroid and all ground truth centroids, map each obtained centroid to the ground truth centroid whose distance is the minimum among all the ground truth centroids. We note that a ground-truth model is often not available in practice since clustering is an unsupervised learning method. As shown in Appendix Figure 11, both models produce the same accuracy ranging from 86% to 99% depending on the initially chosen centroids.

In all experiments, our privacy-preserving model achieves the same accuracy that the plaintext algorithm does. It can be explained as follows: the loss of accuracy of our protocol compared to the plaintext algorithm is solely due to the garble-circuit based-division operation as mentioned above. Moreover, the roundoff/truncation error is very small (e.g. $10^{-4}$). Therefore, the loss of accuracy does not occur in our experiments. However, in the case this error is not very small, we would like to note that the accuracy of our model can be improved by increasing the number of digits used in the division operation. Specifically, during the truncation step, if we keep more digits, the accuracy of our scheme will increase, however, it requires more computation/communication cost. There is a tradeoff between computational time and accuracy of the division operation.

8 Conclusion

In this paper, we presented a novel privacy-preserving $K$-means clustering scheme with an efficient batched secure squared Euclidean distance and a customized garbled circuit to compute the binary secret sharing of the minimum value among a list of secret shared values.

Although our proposed protocol currently takes about 2 hours for clustering 100,000 records, it is practical for many real-world scenarios where privacy is critical to the parties (e.g., medical records of patients/hospitals, customer databases of companies) and the clustering algorithm runs periodically (i.e., no need to be real-time). For example, two hospitals/companies usually just want to train a model in a weekly, monthly, or even quarterly or yearly basis to update knowledge about patients/customers/items in their joint database, to have efficient and dedicated treatments/marketing schemes targeted/tailored for each subgroup (i.e., each cluster). More importantly, it is worth emphasizing that the proposed algorithm is already five orders of magnitude faster than the state-of-the-art work. We believe our work can serve as an important step to facilitate the development of faster privacy-preserving clustering algorithms in the future, especially through MPC.

We finally describe three directions for future work: improving scalability, other applications of secure squared Euclidean distance, and extension to malicious adversaries.

- The current implementation of our scheme only uses single-thread while our proposed protocol can be implemented in a parallel fashion. To enhance scalability, we plan to implement each step of the protocol (Figure 4) in parallel, which allows the scheme to deal with a big dataset (e.g. million points) in minutes.
- We believe that the construction of our SSED is of independent interests, and can be used in many applications such as k-nearest neighbors or face recognition. However, we usually need to tailor the construction for each specific problem.
- Another direction is to extend our scheme to the malicious adversarial setting where the combination of malicious secure computation protocols is a non-trivial problem. For example, it is not known how to efficiently verify parties that use the same shares from the previous k-mean step to the next steps. One promising direction is to investigate the malicious secure SPDZ protocol [13] which uses MACs to achieve malicious security.

A Details of Our Building Blocks

A.1 Revising Communication-Efficient Secure Multiplication Based on 1-out-of-N OT

Recently, several works [33, 34, 42, 47] have proposed efficient protocols to generalize 1-out-of-2 OT extension to 1-out-of-N OT, in which the the receiver learns one of the sender’s N messages. To achieve 1-out-of-N OT, the main modification compared to the original IKNP scheme is the different kinds of encoding used to construct the IKNP OT extension matrices. While IKNP use a 128-bit repetition code, Kolesnikov and Kumaresan [33] employ 256-bit Walsh-Hadamard error-correcting code and achieve 1-out-of-N OT on random strings, for N up to approximately 256. The works [42, 47] use either pseudo-random code or linear BCH code to achieve 1-out-of-N OT for large N. It is important to notice in the 1-out-of-N OT that the number of base OTs have to increase to the codeword length of the underlying code in order to obtain the same computational security level $\kappa = 128$ as in the original 1-out-of-2 OT IKNP. The reason is that the Hamming distance of two codewords has to be at least $\kappa$. For arbitrarily large N and arbitrarily bit length $\ell$ of OT messages, the best 1-out-of-N OT protocol [34] uses 424-448 bits codeword length, which requires 424-448 bits of communication per OT and N hash evaluations. For smaller $\ell$, the best protocols [42, 47] use linear BCH code, in which codeword length depends on $\ell$.

Several works proposed to replace 1-out-of-2 OT with 1-out-of-N OT in some specific problems (e.g. Pri-
vate Set Intersection [34, 42]) to improve their performance. The work [15] proposed a communication efficient Beaver’s triple generation which implicitly improves secure multiplication protocol. Our Section 4.1.1 explicitly described their construction. We now discuss the choice of OT variants, and parameter $N$.

There are two noteworthy aspects of the 1-out-of-$N$ OT based protocol. First, the 1-out-of-$N$ OT protocol of [34, 42, 45–47] is on random strings, in which the protocol itself “chooses” the OT messages $r_i \in [N]$ randomly, gives them to the sender and gives one chosen message $r_b$ to the receiver. In this secure multiplication protocol, we need a standard 1-out-of-$N$ OT protocol where the OT messages $m_i \in [N]$ are given by the sender. To achieve this OT variant, the sender requires to correct the OT random messages by sending $c_i = r_i + m_i$ to the receiver, who later obtains the correct choice message $m_i$ by subtracting $r_b$ from the received $c_i$. This needed step increases the bandwidth requirement of the protocol. Thus, it is necessary to analyze what is the best value for $N$. Second, 1-out-of-2 OT-based protocol can use Correlated OT extension [7] since the sender’s OT inputs $m_{i,0}, m_{i,1}$ are chosen randomly subject to $m_{i,0} + m_{i,1} = 2y$. Doing so reduces the communication cost from the sender to the receiver by a factor of $\frac{1 + \ell}{\kappa + 2\ell}$. This correlated OT idea can be used in the 1-out-of-$N$ OT-based protocol. As a result, we reduce the bandwidth requirement by a factor of $\frac{\ell + N(N-1)/\kappa}{\kappa + N\ell}$.

Table 6 presents the communication cost the 1-out-of-$N$ OT-based secure multiplication of two $\ell$-bit strings. The required codeword length and the best error-correcting code are chosen according to [1] to achieve Hamming distance of two codewords at least $\kappa$. For short bit-length $\ell = 8$ or $\ell = 16$, Table 6 shows that using 1-out-of-$2^4$ OT gives us the best communication cost for secure multiplication, which is $1.2 - 1.51 \times$ lower bandwidth requirement than the original 1-out-of-2 OT-based one. For bigger $\ell$, an incremental improvement is achieved by employing 1-out-of-$2^2$ OT in the secure multiplication protocol.

### A.2 SESD Details

The formal details of our SESD protocol are given in Figure 6. It closely follows and formalizes the detail presented in sections 4.2 and 4.1.2. The security of our construction follows in a straightforward way from the security of its building block (e.g. oblivious transfer) and the encryption scheme. Thus, we omit the proof of the following theorem.

### A.3 Comparison with [54]

We evaluate our prototype on 2D synthetic dataset S1 [16], which was evaluated in [54] for differentially privacy setting. We obtained the implementations of Su et al. scheme [54] from the author’s website, and evaluate their protocol on our own machine, described in Section 7.1 (a single server with 2x 36-core Intel Xeon 2.30GHz CPU and 256GB of RAM). We note that the implementation [54] is in Python.

Typically, training a differentially privacy ML model is much faster than training semi-honest ML. We are interested to examine the performance gap between our scheme and this security model. The experimental results in Table 5 show that our privacy-preserving K-means clustering scheme is only $63.5 \times$ slower than the differential privacy model [54]. Concretely, our protocol requires 1472.6 seconds to evaluate the model on 2D synthetic dataset S1 while the differential privacy model [54] requires 23.8 seconds.

### B Figure Details
PARAMETERS:
- Number of iterations $K$; number of clusters $K$; number of data points $n$; dimension $d$; value $N$
- Ideal OT primitive defined in Figure 7
- An encryption/decryption scheme $Enc, Dec$ (e.g., AES)

INPUT OF ALICE: Arithmetic secret shares $P^A = \{P^A_1, P^A_2, \ldots, P^A_n\}$ of $n$ points $P = \{P_1, P_2, \ldots, P_n\}$

INPUT OF BOB: Arithmetic secret shares $P^B = \{P^B_1, P^B_2, \ldots, P^B_n\}$ of $n$ points $P$

PROTOCOL:
1. For each secret shares $P^A_i \in P^A$:
   - Alice uses an $N$-based representation and rewrites $P^A_i = \sum_{j=0}^{[\ell/\log(N)]-1} N\rho^A_i[j]$
   - Parties invoke $[\ell/\log(N)]$ instances of 1-out-of-$N$ OT as follows:
     - Bob acts as an OT sender with input sequence $(\Delta_{i,j,0}^A, \ldots, \Delta_{i,j,N-1}^A)$ which are randomly chosen from $Z_{2\ell}$
     - Alice acts as an OT receiver with choice value $P^A_j[i]$, and obtains $\Delta_{i,j}^A P^A_i[j]$

2. For each secret shares $P^B_i \in P^B$:
   - Bob uses an $N$-based representation and rewrites $P^B_i = \sum_{j=0}^{[\ell/\log(N)]-1} N\phi^B_i[j]$
   - Parties invoke $[\ell/\log(N)]$ instances of 1-out-of-$N$ OT as follows:
     - Alice acts as an OT sender with input sequence $(\Delta_{i,j,0}^B, \ldots, \Delta_{i,j,N-1}^B)$ which are randomly chosen from $Z_{2\ell}$
     - Bob acts as an OT receiver with choice value $P^B_j[i]$, and obtains $\Delta_{i,j}^B P^B_i[j]$

3. For each iteration $t \in T$:
   - INPUT OF ALICE: Arithmetic secret shares $\{\phi^A_1, \phi^A_2, \ldots, \phi^A_k\}$ of $K$ centroids $\{\phi_1, \ldots, \phi_k\}$
   - INPUT OF BOB: Arithmetic secret shares $\{\phi^B_1, \phi^B_2, \ldots, \phi^B_k\}$ of $K$ centroids $\{\phi_1, \ldots, \phi_k\}$

I. Sub-protocol: computing the first term of the mixed term in formula (2)
   (1) For each $i \in [N]$:
      - For each $k \in K$, Bob defines $y_{i,k} := P^B_i[p] - \phi^B_i[p]$
      - For $j \in [\ell/\log(N)]$ and $\theta \in [N]$, Bob computes encryptions $e_{i,j,\theta} = Enc(\Delta_{i,j,\theta}^B m_{j,\theta,1} m_{j,\theta,2} \cdots m_{j,\theta,K})$ where for all $m_{j,\theta,k} \in [K]$ is randomly chosen from $Z_{2\ell}$; for $1 \leq \theta \leq N - 1$, $m_{j,\theta,k} = (N^2 \theta_t k - m_{j,0,k}) \mod 2\ell$
   (2) Bob sends to Alice the ciphertexts $e_{i,j,\theta}$ in order.
   (3) For each $i \in [N]$ and $j \in [\ell/\log(N)]$, Alice decrypts the ciphertexts $e_{i,j,\theta}$ using the decrypted key $\Delta_{i,j,\theta}$
      where $\tilde{\omega}_i := P^A_i[j]$, and obtains $m_{j,\tilde{\omega}_i,1} m_{j,\tilde{\omega}_i,2} \cdots m_{j,\tilde{\omega}_i,K}$
   (4) For each $i \in [N]$ and $k \in [K]$, Alice locally computes $z^A_{i,k} := \sum_{j=0}^{[\ell/\log(N)]-1} m_{j,\tilde{\omega}_i,k} \mod 2\ell$
   (5) For each $i \in [N]$ and $k \in [K]$, Bob locally computes $z^B_{i,k} := \sum_{j=0}^{[\ell/\log(N)]-1} m_{j,\tilde{\omega}_i,k} \mod 2\ell$ respectively.

II. Sub-protocol: computing the second term of the mixed term in formula (2)
   (1) For each $i \in [N]$:
      - For each $k \in K$, Alice defines $y_{i,k} := P^A_i[p]$
      - For $j \in [\ell/\log(N)]$ and $\theta \in [N]$, Alice computes encryptions $e_{i,j,\theta} = Enc(\Delta_{i,j,\theta}^A m_{j,\theta,1} m_{j,\theta,2} \cdots m_{j,\theta,K})$ where for all $m_{j,\theta,k} \in [K]$ is randomly chosen from $Z_{2\ell}$; for $1 \leq \theta \leq N - 1$, $m_{j,\theta,k} = (N^2 \theta_t k - m_{j,0,k}) \mod 2\ell$
   (2) Alice sends to Bob the ciphertexts $e_{i,j,\theta}$ in order.
   (3) For each $i \in [N]$ and $j \in [\ell/\log(N)]$, Bob decrypts the ciphertexts $e_{i,j,\theta}$ using the decrypted key $\Delta_{i,j,\theta}$
      where $\tilde{\theta}_i := P^B_i[j]$, and obtains $m_{j,\tilde{\theta}_i,1} m_{j,\tilde{\theta}_i,2} \cdots m_{j,\tilde{\theta}_i,K}$
   (4) For each $i \in [N]$ and $k \in [K]$, Bob locally computes $u^A_{i,k} := \sum_{j=0}^{[\ell/\log(N)]-1} m_{j,\tilde{\theta}_i,k} \mod 2\ell$
   (5) For each $i \in [N]$ and $k \in [K]$, Alice locally computes $u^B_{i,k} := \sum_{j=0}^{[\ell/\log(N)]-1} m_{j,\tilde{\theta}_i,k} \mod 2\ell$ respectively.

III. Sub-protocol: outputting arithmetic secret sharings of the output $F_{Dist}(P_1, \phi_{tk})$
   (1) For each $k \in [K]$, Parties invoke a standard secure multiplication to compute the third terms $\phi^B_k[p] \phi^A_k[p]$ of Eq. (2), and obtains an output under a secret share form as $v^A_k$ and $v^B_k$, respectively.
   (2) For each $i \in [N], k \in [K]$, Alice outputs $\sum_{p=1}^{d} (P^A_i[p] - \phi^A_k[p])^2 + z^A_{i,k} + u^A_{i,k} + v^A_k$ as a secret share of $F_{Dist}(P_1, \phi_{tk})$
   (3) For each $i \in [N], k \in [K]$, Bob outputs $\sum_{p=1}^{d} (P^B_i[p] - \phi^B_k[p])^2 + z^B_{i,k} + u^B_{i,k} + v^B_k$ as a secret share of $F_{Dist}(P_1, \phi_{tk})$

Fig. 6. Our Secure Euclidean Squared Distance (SESD) Construction in the Sequential Amortized Setting.
Practical Privacy-Preserving K-means Clustering

Parameters: A bit length $m$, and two parties: sender $S$ and receiver $R.$

Functionality:

- Wait for pair-input $(x_0, x_1) \in \{0, 1\}^m$ from $S$
- Wait for bit-input $b \in \{0, 1\}$ from $R$
- Give output $x_b$ to the receiver $R.$

Fig. 7. Oblivious Transfer functionality $OT_m.$

Parameters: A bit length $m$, a function $f$, and two parties: sender $S$ and receiver $R.$

Functionality:

- Wait for input $x \in \{0, 1\}^*$ from $S$
- Wait for input $y \in \{0, 1\}^*$ from $R$
- Give output $f(x, y)$ to the receiver $R.$

Fig. 8. Garbled circuit functionality $GC(x, y, f).$

Fig. 9. Matrix transposition of a matrix $C.$

Fig. 10. Comparison of accuracy for privacy-preserving, plain-text, and ground truth model. Our privacy-preserving model achieves the same accuracy as the plain-text model, which reaches 95% accuracy compared to the expected ideal clusters.

Fig. 11. Comparison of accuracy for privacy-preserving, plain-text, and ground truth model. Our privacy-preserving model achieves the same accuracy as the plain-text model, which reaches $86.84\%$ and $91.68\%$ accuracy compared to the expected ideal clusters. The 99% accuracy privacy-preserving model is almost exactly the ground truth model in Figure 11a.
