**Updatable Private Set Intersection**

**Abstract:** Private set intersection (PSI) allows two mutually distrusting parties each with a set as input, to learn the intersection of both their sets without revealing anything more about their respective input sets. Traditionally, PSI studies the static setting where the computation is performed only once on both parties’ input sets. We initiate the study of updatable private set intersection (UPSI), which allows parties to compute the intersection of their private sets on a regular basis with sets that also constantly get updated. We consider two specific settings. In the first setting called UPSI with addition, parties can add new elements to their old sets. We construct two protocols in this setting, one allowing both parties to learn the output and the other only allowing one party to learn the output. In the second setting called UPSI with weak deletion, parties can additionally delete their old elements every $t$ days. We present a protocol for this setting allowing both parties to learn the output. All our protocols are secure against semi-honest adversaries and have the guarantee that both the computational and communication complexity only grow with the set updates instead of the entire sets. Finally, we implement our UPSI with addition protocols and compare with the state-of-the-art PSI protocols. Our protocols compare favorably when the total set size is sufficiently large, the new updates are sufficiently small, or in networks with low bandwidth.

**1 Introduction**

Private set intersection (PSI) enables two parties, each holding a private set of elements, to compute the intersection of the two sets while revealing nothing more than the intersection itself. Over the years, PSI and its related functionalities have found many real-world privacy-preserving applications including DNA testing and pattern matching [TPKC07], remote diagnostics [BPSW07], online advertising [IKN+20], password breach alerting [TPY+19], mobile private contact discovery [KRS+19], privacy-preserving contact tracing [TSS+20, CCF+20], and many more. There has been tremendous progress made towards realizing PSI efficiently [KKRT16, RR17, CLR17, PRTY19, CM20, PRTY20] with both semi-honest and malicious security.

Despite tremendous advancements and improvements in the efficiency of PSI protocols, one drawback of all the existing protocols is that when parties update their sets to include some new elements or remove certain existing elements, in order to compute the intersection between the two updated sets, parties have to perform a fresh PSI computation every time. This incurs a lot of wasteful computational and communication overhead, especially in scenarios where the updates are done very frequently and/or the updates to the existing sets are small. Indeed, in a lot of real-world scenarios such as aggregated ads measurement [IKN+20], password breach monitoring [APP, MIC], digital contact tracing [TSS+20, CCF+20], PSI is performed on a regular (e.g., daily) basis with updated sets, where the daily update to the sets could be very small compared to the entire sets. In this work, we ask the following question:

*Can we design protocols that allow parties to regularly update their sets and perform PSI where every time both the computation and communication costs are only proportional to their updates instead of the entire sets?*

**1.1 Our Results**

We first formalize the notion of **updatable private set intersection (UPSI)** as a special case of secure two-party computation with a reactive functionality that interacts with both parties over many days and keeps its own private internal state between days. There are two types of updates to consider: adding new elements and deleting existing elements. In particular, we consider the following two settings and present three constructions summarized in Table 1.
Table 1. Summary of our protocols. \( N \) denotes the size of the old sets and \( N' \) denotes the size of the updates. \( t \) denotes the number of days when parties refresh their sets in UPSI with weak deletion. \( O^*(\cdot) \) denotes amortized complexity.

1.1.1 UPSI with Addition

In the first setting, on every day, we allow both parties to add a new set of elements to their existing old sets. The output on each day is the intersection of the two updated entire sets. We construct two protocols:

- **Two-Sided UPSI with Addition**: A Diffie-Hellman based protocol that allows both parties to receive the output on each day. Both the computational and communication complexity of this protocol only grow linearly with the size of the added new sets and are independent of the size of the old sets.

- **One-Sided UPSI with Addition**: An additively homomorphic encryption based protocol that allows only one party to receive the output. The overall complexity may vary on different days, hence we consider the amortized cost per day over a long period of days. Both the amortized computational and communication complexity of this protocol only grow linearly with the size of the added new sets and logarithmically with the size of the old sets. Technically, we develop an ORAM-like tree structure that allows one party to obliviously update an encrypted database and another party to obliviously search on the encrypted database (where the secret key is held by the first party), which may be of independent interest.

Note that one-sided UPSI with addition is a stronger functionality in the semi-honest setting because the output-receiving party can send the output to the other party so as to achieve two-sided output. We present a protocol for one-sided UPSI with addition because the functionality may be desirable in many server-client applications where only the client is allowed to learn the output (e.g., password breach monitoring [APP, MIC]).

1.1.2 UPSI with Weak Deletion

In the second setting, we additionally allow both parties to refresh their sets every \( t \) days. Namely, they will add a set of elements to their sets every day, and delete elements that were added to their sets \( t \) days ago. This setting is motivated by applications such as privacy-preserving contact tracing [TSS+20, CCF+20] where data about people’s interactions from more than e.g. 14 days ago is no longer useful. In this example, one party’s (server’s) input is the set of people who tested positive on that day, the other party’s (client’s) input is the set of people they interacted with on that day. The output on each day is the list of people the client interacted with in the last \( t \) days, who also tested positive in the last \( t \) days.

We construct an oblivious transfer (OT) based protocol that allows both parties to receive the output. Both the computational and communication complexity grow linearly with the size of the added new sets and \( t \).

1.1.3 Experiments

We implement the two UPSI with addition protocols and compare with the state-of-the-art PSI protocols. To demonstrate the updatable property, we consider the following setting: each party initially holds an empty set. Then, on every new day, both parties add a new set of size \( N' \) to their existing sets and wish to learn the updated set intersection. We repeat this process over a period of several days (\( \frac{N}{N'} \)) till the total set size of each party is \( N \). We compare the amortized (over the total number of days) communication cost and running time of our protocol with the prior PSI protocols [KKRT16, PRTY19, CM20], where, on any day, the two parties run a fresh PSI on their updated sets to learn the updated intersection.

Generally speaking, the (concrete/amortized) communication cost of both our protocols only grows with \( N' \) and at most logarithmically with \( N \), hence we have more advantages in efficiency when the total set size \( N \) is larger, the update size \( N' \) is smaller, and the network bandwidth is lower. In particular, our two-sided UPSI with addition protocol beats all the PSI protocols in communication by \( 7.5 – 13250 \times \) in the settings we consider (where \( N \gg N' \)). As an example for running time, when \( N = 2^{20} \) and \( N' = 2^{10} \), our protocol beats the best PSI protocol by \( 1.1 – 7.6 \times \) for network bandwidth between 5 – 50 Mbps. Our one-sided UPSI with addition protocol beats the PSI protocols in communication...
by $2 - 149 \times$ in almost all settings we consider. As an example for running time, when $N = 2^{20}$ and $N' = 2^6$, our protocol beats the best PSI protocol by $1.8 - 30.5 \times$ for network bandwidth between $5 - 50$ Mbps.

### 1.2 Related Work

There are various approaches in achieving efficient semi-honest PSI in different settings, including Diffie-Hellman-based [Mea86, HFH99], fully homomorphic encryption (FHE)-based [CLR17], circuit-based [HEK12, PSSZ15, PSWW18, PSTY19], and oblivious transfer (OT)-based [KKRT16, PRTY19, CM20] protocols. We refer the reader to [PSZ14, PSZ18] for an overview of the different paradigms for PSI. Protocols based on OT [KKRT16, PRTY19, CM20] are currently the fastest in practice because they can take advantage of the efficient implementation of OT extension [IKNP03, ALSZ13].

In the updatable setting, the work of Kiss et al. [KLS+17] studies PSI with pre-computation between a server with a large set of size $N$ and a client with a small set of size $N'$. In a setup phase, the communication and computation cost is linear in $N$ while in the online phase the cost is only linear in $N'$. It allows the server to update its set without recomputing the setup phase and the client to run the online phase for new sets. Nevertheless, they do not provide an ideal functionality for the updatable setting that captures the exact leakage from their protocols. In particular, if the client’s sets in the online phase are $X_1, \ldots, X_d$ and the server’s updates are $Y_1, \ldots, Y_d$, then all of their protocols reveal to the client $X_i \cap Y_j$ for all $i, j$. Such leakage also arises in our attempt to extend the Diffie-Hellman-based PSI to the updatable setting, which we discuss in Section 1.3. In this work, we formalize security by a reactive ideal functionality that prevents such leakage in the updatable setting.

A recent work of Abadi et al. [ATD20] studies delegated PSI protocols that support data updates and multi-party PSI. In particular, clients can upload their (encrypted) private data to a server and outsource the PSI computation. Clients can update their sets with communication and computation only growing with their updates. However, both the computation and communication of the PSI protocol grow with the entire sets, and they require the existence of a server.

### 1.3 Challenges and Ideas

We briefly explain the technical challenges in the design of our protocols. We start with the addition-only setting. Let $X, Y$ denote the old sets of the two parties $P_0, P_1$ respectively, and let $X', Y'$ denote their new added sets. For simplicity, assume $|X| = |Y| = N$ and $|X'| = |Y'| = N'$. Recall that we are mostly interested in the scenario when $N \gg N'$ and our goal is to make the computation and communication cost to learn the new intersection only grow with $N'$ and not $N$ (except with logarithmic factors).

First, note that naturally extending existing FHE-based [CLR17], circuit-based [HEK12, PSSZ15, PSWW18, PSTY19], or OT-based [KKRT16, PRTY19, CM20] PSI protocols does not work. In the FHE-based protocols, while $P_0$ (the output-receiving party) can send $\text{Enc}(X')$ which only grows with $N'$, the computation cost of $P_1$ would involve homomorphically evaluating to compare with his entire input set $Y \cup Y'$ (and also homomorphically compare $Y'$ with $P_1$’s old set $X$), which grows with $N$. A similar issue arises in circuit-based protocols where in fact, communication also grows with $N$. The OT-based protocols require one party to fix its input set and the number of OTs (to set up the oblivious pseudorandom function) depends on $N$, so both communication and computation would grow.

#### 1.3.1 Two-Sided UPSI

On first thought, the Diffie-Hellman-based protocol [Men86, HFH99] seems more promising because it has special algebraic structures that may be suitable for the updatable setting. To briefly recall the protocol, let $X, Y$ be $P_0$ and $P_1$’s input sets, respectively. Both parties first hash their elements into a group where DDH holds, namely $H(X)$ and $H(Y)$. Each party picks a secret exponentiation key, that is $k_0$ and $k_1$ respectively. $P_1$ then sends $H(Y)^{k_1}$ and $P_0$ responds back with $H(X)^{k_0 k_1}$. Symmetrically, they can obtain $H(X)^{k_0 k_1}$. By comparing $H(Y)^{k_0 k_1}$ and $H(X)^{k_0 k_1}$, both parties can compute the intersection $X \cap Y$. In the updatable setting, they can repeat this process on their new elements $X', Y'$ ensuring that computation and communication only grow with the size of the new sets. Unfortunately, this naïve adaption to the updatable setting does not trivially solve the problem as it leaks extra information than what the parties can learn from the ideal functionality. In particular, it leaks $X' \cap Y$ and $X' \cap Y'$ to $P_0$, which is not available in the ideal world.

Our solution is to get rid of such leakage by investigating what can be inferred from the ideal functionality and leveraging the nice algebraic structures. In particular, we split the updated output into two parts, one of which (that is, $X \cap Y'$) can be computed by extend-
ing the above DDH-based protocol and for the other (in particular, $X' \cap (Y \cup Y')$), we run a fresh PSI instance on small input sizes. We carefully choose this split and design the appropriate sub-protocols to ensure no information is leaked. We refer to Section 4 for a detailed overview and the formal construction.

### 1.3.2 One-Sided UPSI

In our protocol above, we crucially rely on the fact that both parties learn the output on each day. In particular, even if we want only $P_0$ to learn output, to ensure that $P_1$ uses a small input for the fresh PSI, we require $P_1$ to learn the output of the first part that extends the DDH-based approach. We now focus on the challenges and ideas in designing a protocol for one-sided UPSI where only $P_0$ learns the output. At a high level, our key idea is for $P_1$ to store an encrypted version of his set on $P_0$’s storage and on each day, he updates this encrypted database based only on his new input $Y'$. Then, we require a mechanism that allows $P_0$ to obliviously query this database and compute on the encrypted data (by interacting with $P_1$) to learn the intersection without leaking any information to $P_1$.

We discuss one natural idea to implement this mechanism using FHE. Suppose $P_1$ uses FHE to encrypt $Y$ and stores $\text{Enc}(Y)$ on $P_0$. Then $P_0$ can use her inputs to homomorphically compute $\text{Enc}(X \cap Y)$. Both parties can then run a secure two-party computation (2PC) protocol where $P_0$’s input is $\text{Enc}(X \cap Y)$ and $P_1$’s input is secret key $sk$, from which $P_0$ learns the output ($X \cap Y$). When there is update, $P_1$ can update the encrypted database by sending $\text{Enc}(Y')$ and $P_0$ can learn $(X' \cap (Y \cup Y'))$ with communication only growing with $N$. However, $P_0$’s homomorphic computation still grows with $N$. Moreover, it requires expensive FHE evaluation and 2PC for FHE decryption.

To implement this approach efficiently, we take inspiration from oblivious RAM [SvDS+18]. The crucial idea is that the encrypted database is maintained in a tree structure where, on any day, $P_1$ only updates one level of the tree and $P_0$ only queries on one path of the tree, so the (amortized) cost only grows with the depth of the tree (logarithmic in $N$ and not linear). We also build an efficient 2PC protocol for decryption using additively homomorphic encryption instead of FHE. We further optimize our protocol by using Cuckoo hashing [PR04] to store elements in each node of the tree and leveraging the structure of El Gamal encryption [Gam84] in our context. We refer to Section 5 for more details.

### 1.3.3 Weak Deletion

We make an interesting observation about OT-based PSI protocols [KKRT16, PRTY19, CM20]. They work in a streaming setting where, in a setup phase, only the output-receiving party’s input set is known. Then, the sender’s inputs can be fed in a streaming manner and the protocol allows the receiver to learn the intersection for each stream. We directly take advantage of this streaming structure and build on these protocols to design our weak deletion protocol. We refer to Section 6 for an overview and the construction.

### 2 Preliminaries

**Notation.** We use $\lambda, \sigma$ to denote the computational and statistical security parameters, respectively. By $\text{negl}(\lambda)$ we denote a negligible function, i.e., a function $f$ such that $f(\lambda) < 1/p(\lambda)$ holds for any polynomial $p(\cdot)$ and sufficiently large $\lambda$. By $\approx$ we mean two distributions are computationally indistinguishable. Let $\mathbb{N}^+$ denote the list of positive integers and $\mathbb{N}$ denote $\mathbb{N}^+ \cup \{0\}$.

**Cuckoo Hashing.** We define Cuckoo Hashing [PR04] verbatim from [KKRT16]. To assign $n$ items into $b$ bins, first choose random functions $H_1, H_2, H_3 : \{0,1\}^* \rightarrow [b]$ and initialize empty bins $B[1, \ldots, b]$. To hash an item $x$, first check to see whether any of the bins $B[H_1(x)], B[H_2(x)], B[H_3(x)]$ are empty. If so, place $x$ in one of the empty bins and terminate. Otherwise, choose a random $i \in \{1, 2, 3\}$, evict the item currently in $B[H_i(x)]$, replacing it with $x$, and then recursively try to insert the evicted item. If this process does not terminate after a certain number of iterations, then the final evicted element is placed in a special bin called stash.

We define private set intersection, additively homomorphic encryption and the Decisional Diffie-Hellman (DDH) assumption in Appendix A.

### 3 Updatable PSI

In this section, we formalize the definition of Updatable Private Set Intersection (UPSI). Consider two parties $P_0$ and $P_1$ who wish to run PSI on a daily basis with updated sets each day. We consider two settings on how they can update their sets. The first setting, which we call UPSI with addition, allows both parties to add a set of elements to their respective sets each day. In the second setting, which we call UPSI with weak deletion, both parties can add a set of elements to their sets every day and delete elements that were added to their set $t$
days before. In other words, each party only holds the elements added in the most recent \( t \) days. Moreover, on each day, the output learnt is only the intersection of each party’s new elements with the last \( t \) days’ elements of the other party.

### 3.1 UPSI with Addition

In the setting of UPSI with addition, two parties \( P_0 \) and \( P_1 \) each hold a private set and add new elements to their respective sets each day. They want to jointly compute their set intersection every day on their updated sets without revealing anything beyond that. We formalize UPSI with addition as a special case of secure two-party computation with a reactive functionality defined in Figure 1. For simplicity, we assume that each party adds the same number of elements as the other party on each day.

We consider two output scenarios: in two-sided UPSI with addition \( F_{\text{UPSI-add-two}} \), both parties obtain output at the end of each day; in one-sided UPSI with addition \( F_{\text{UPSI-add-one}} \), only \( P_0 \) gets the output. Note that in the semi-honest model, a secure protocol achieving \( F_{\text{UPSI-add-one}} \) can be easily transformed into one achieving \( F_{\text{UPSI-add-two}} \) by \( P_0 \) sending the output to \( P_1 \) at the end, hence \( F_{\text{UPSI-add-one}} \) is a stronger notion in the semi-honest model.

**Initialization:** \( X := \emptyset \), \( Y := \emptyset \).

**Day \( d \):**
- **Public parameter:** The set size on Day \( d \) is \( N_d \).
- **Inputs:**
  - \( P_0 \) inputs a set \( X_d \) of size \( N_d \) where each element is from \( \{0, 1\}^* \), and \( X_d \cap X = \emptyset \).
  - \( P_1 \) inputs a set \( Y_d \) of size \( N_d \) where each element is from \( \{0, 1\}^* \), and \( Y_d \cap Y = \emptyset \).
- **Update:** On receiving the inputs from both parties, the ideal functionality updates \( X := X \cup X_d \), \( Y := Y \cup Y_d \) and computes \( I_d = X \cap Y \).
- **Output:**
  - In \( F_{\text{UPSI-add-two}} \), the ideal functionality sends \( I_d \) to both parties.
  - In \( F_{\text{UPSI-add-one}} \), the ideal functionality sends \( I_d \) to only \( P_0 \).

Fig. 1. Ideal functionalities \( F_{\text{UPSI-add-two}} \) and \( F_{\text{UPSI-add-one}} \) for UPSI with addition.

Consider the first \( D \) days: let \( X_{[D]} = \{X_1, \ldots, X_D\} \) be the inputs of \( P_0 \) and \( Y_{[D]} = \{Y_1, \ldots, Y_D\} \) be the inputs of \( P_1 \). Let View\(^{\Pi,D}_{\text{add}}(X_{[D]}, Y_{[D]}) \) and Output\(^{\Pi,D}_{\text{add}}(X_{[D]}, Y_{[D]}) \) be the view and outputs of \( P_b \) (\( b \in \{0, 1\} \)) in the protocol \( \Pi \) at the end of \( D \) days, respectively. Let \( f(X_{[D]}, Y_{[D]}) := \{I_1, \ldots, I_D\} \) be the outputs of the ideal functionality in the \( D \) days.

**Definition 3.1. (Two-Sided UPSI with Addition.)** A protocol \( \Pi \) is semi-honest secure with respect to ideal functionality \( F_{\text{UPSI-add-two}} \) if there exists PPT simulators \( \text{Sim}_0 \) and \( \text{Sim}_1 \) such that for any \( D \in \mathbb{N}^+ \), any inputs \( (X_{[D]}, Y_{[D]}) \),

1. \( \text{Sim}_0(\lambda) \approx \) View\(^{\Pi,D}_{\text{add}}(X_{[D]}, Y_{[D]}), \text{Out}^{\Pi,D}_{\text{add}}(X_{[D]}, Y_{[D]})) \approx \text{Sim}_0(1^\lambda, X_{[D]}, f(X_{[D]}, Y_{[D]})) \)

2. \( \text{Sim}_1(\lambda) \approx \) View\(^{\Pi,D}_{\text{add}}(X_{[D]}, Y_{[D]}), \text{Out}^{\Pi,D}_{\text{add}}(X_{[D]}, Y_{[D]})) \approx \text{Sim}_1(1^\lambda, Y_{[D]}, f(X_{[D]}, Y_{[D]})) \).

**Definition 3.2. (One-Sided UPSI with Addition.)** \( \Pi \) is semi-honest secure with respect to ideal functionality \( F_{\text{UPSI-add-one}} \) if there exists PPT simulators \( \text{Sim}_0 \) and \( \text{Sim}_1 \) such that for any \( D \in \mathbb{N}^+ \), any inputs \( (X_{[D]}, Y_{[D]}) \),

1. \( \text{Sim}_0(\lambda) \approx \) View\(^{\Pi,D}_{\text{add}}(X_{[D]}, Y_{[D]})) \approx \text{Sim}_0(1^\lambda, X_{[D]}, f(X_{[D]}, Y_{[D]})) \)

2. \( \text{Sim}_1(\lambda) \approx \) View\(^{\Pi,D}_{\text{add}}(X_{[D]}, Y_{[D]}), \text{Out}^{\Pi,D}_{\text{add}}(X_{[D]}, Y_{[D]})) \approx \text{Sim}_1(1^\lambda, Y_{[D]}, f(X_{[D]}, Y_{[D]})) \).

### 3.2 UPSI with Weak Deletion

In the setting of UPSI with weak deletion, two parties \( P_0 \) and \( P_1 \) each hold a private set. Then, on each day, they add new elements to their respective sets and delete elements that were added \( t \) days before. On each day, they want to jointly compute the union of the intersection between their new elements and the other party’s updated set comprising elements from the last \( t \) days, without revealing anything beyond that. We formalize UPSI with weak deletion as a special case of secure two-party computation with a reactive functionality defined in Figure 2. For simplicity, we assume that each party adds the same number of elements as the other party on each day. We only consider two-sided output where both parties receive the output every day.

Consider the first \( D \) days: let \( X_{[D]} = \{X_1, \ldots, X_D\} \) be the inputs of \( P_0 \) and \( Y_{[D]} = \{Y_1, \ldots, Y_D\} \) be the inputs of \( P_1 \) and \( N_{[D]} = \{N_1, \ldots, N_D\} \) be the set sizes. Let View\(^{\Pi,D}_{\text{del}}(X_{[D]}, Y_{[D]}) \) and Output\(^{\Pi,D}_{\text{del}}(X_{[D]}, Y_{[D]}) \) be the view and outputs of \( P_b \) (\( b \in \{0, 1\} \)) in the protocol \( \Pi \) at the end of \( D \) days, respectively. Let \( f(X_{[D]}, Y_{[D]}) := \{I_1, \ldots, I_D\} \) be the ideal functionality’s output in \( D \) days.

**Definition 3.3. (UPSI with Weak Deletion.)** A protocol \( \Pi \) is semi-honest secure with respect to ideal functionality \( F_{\text{UPSI-del}} \) if there exists PPT simulators
Initialization: \( X := \emptyset, Y := \emptyset. \)

Day \( d \):
- **Public parameter:** The set size on Day \( d \) is \( N_d \).
- **Inputs:**
  - \( P_0 \) inputs a set \( X_d \) of size \( N_d \) where each element is from \( \{0, 1\}^* \), and \( X_d \cap X = \emptyset. \)
  - \( P_1 \) inputs a set \( Y_d \) of size \( N_d \) where each element is from \( \{0, 1\}^* \), and \( Y_d \cap Y = \emptyset. \)
- **Update:** On receiving the inputs from both parties, the ideal functionality updates \( X := (X \cup X_d) \setminus X_{d-1} \) and computes \( I_d = (X \cap Y) \cup (X \cap Y_d) \).
  - (If \( d - t \leq 0 \), let \( X_{d-t} = Y_{d-t} = \emptyset. \))
- **Output:** The ideal functionality sends \( I_d \) to both parties.

![Fig. 2. Ideal functionality \( \mathcal{F}_{UPSI-del} \) for UPSI with weak deletion.](image)

Sim0 and Sim1 such that for any \( d \in \mathbb{N}^+ \), any inputs \( (X_{[d]}, Y_{[d]}) \),
1. \((View_{0}^{1, 1, D}(X_{[d]}, Y_{[d]}), Out_{0}^{1, 1, D}(X_{[d]}, Y_{[d]})) \approx (Sim_{0}(1\lambda, X_{[d]}, N_{[d]}, f(X_{[d]}, Y_{[d]})), f(X_{[d]}, Y_{[d]}))\).
2. \((View_{1}^{1, 1, D}(X_{[d]}, Y_{[d]}), Out_{1}^{1, 1, D}(X_{[d]}, Y_{[d]})) \approx (Sim_{1}(1\lambda, Y_{[d]}, N_{[d]}, f(X_{[d]}, Y_{[d]})), f(X_{[d]}, Y_{[d]}))\).

Finally, we discuss an alternative ideal functionality for weak deletion and why we choose \( \mathcal{F}_{UPSI-del} \) with motivating examples in Appendix B.

### 4 Two-Sided UPSI with Addition

In this section, we present a two-sided UPSI with addition protocol satisfying Definition 3.1 based on the DDH assumption in the random oracle model.

**4.1 Construction**

**Notation.** Let \( G \) be a group of prime order \( q \) with generator \( g \). Let \( H : \{0, 1\}^* \rightarrow G \) be a hash function. For a set \( X \subseteq \{0, 1\}^* \), we denote \( H(X) := \{H(x) \mid x \in X\} \) and \( H(X)^k := \{H(x)^k \mid x \in X\} \).

**Construction Overview.** Our starting point is the semi-honest PSI protocol based on the DDH assumption [Mea86, HFH99]. The protocol roughly works as follows. Both parties first hash their elements into a group where DDH holds, namely \( P_0 \) and \( P_1 \) compute \( H(X) \) and \( H(Y) \) respectively. Each party holds a secret exponentiation key, that is, \( P_0 \) holds \( k_0 \) and \( P_1 \) holds \( k_1 \). The parties then use their keys to exponentiate their hashed elements and exchange the results. They further exponentiate the elements in the received set and send back the results. At the end, both parties obtain \( H(X)^{k_0 k_1} \) and \( H(Y)^{k_0 k_1} \), from which they can derive the intersection \( X \cap Y \).

In the updatable setting, to learn the updated intersection \( I_d \) on each Day \( d \), parties only need to learn the update set \( I_{update} = I_d \setminus I_{d-1} \). Observe that \( I_{update} \) can be split into two disjoint sets, \( I_{X, old} = X_{old} \cap Y_d \) (where \( X_{old} := X_{[d-1]} \setminus I_{d-1} \) and \( I_{X, new} = X_d \cap Y_d \)), both of which can be inferred by \( P_0 \) from the output of the ideal functionality and its own input. Therefore, it suffices to let \( P_0 \) learn both \( I_{X, old} \) and \( I_{X, new} \). Symmetrically, if we let \( I_{Y, old} := Y_{[d-1]} \setminus I_{d-1} \), then \( I_{update} \) can also be split into \( I_{Y, old} = Y_{old} \cap X_d \) and \( I_{Y, new} = Y_d \setminus X_d \) to allow \( P_1 \) to compute the output.

Using the ideas from the above DDH-based protocol, we first ensure that \( P_0 \) holds a set \( H(X_{old})^{k_0 k_1} \) at the end of Day \( (d-1) \), where \( X_{old} = X_{[d-1]} \setminus I_{d-1} \). Then on Day \( d \), \( P_1 \) sends \( H(Y_d)^{k_0 k_1} \) and \( P_0 \) computes \( H(Y_d)^{k_0 k_1} \). From this, \( P_0 \) can derive \( I_{X, old} = X_{old} \cap Y_d \). Symmetrically, \( P_1 \) can learn \( I_{Y, old} = Y_{old} \cap X_d \).

The next objective is to let \( P_0 \) learn \( I_{X, new} = X_{new} \cap Y_d \). Naively, the two parties can run a PSI protocol between the two sets \( X_d \) and \( Y_{[d]} \), but the computational cost of \( P_1 \) would grow at least linearly with the size of \( Y_{[d]} \), which is unsatisfactory. Observe that \( I_{X, new} \) can also be split into two disjoint sets, \( X_d \cap Y_d \) and \( X_d \cap Y_{[d-1]} \), the latter being exactly \( I_{Y, old} \).

A natural idea is to first run a PSI between \( X_d \) and \( Y_d \) so that \( P_0 \) can learn \( X_d \cap Y_d \) and then let \( P_1 \) send \( I_{Y, old} \) to \( P_0 \). Unfortunately, this idea does not work because it leaks extra information to \( P_0 \) (observe that \( P_0 \) does not learn \( X_d \cap Y_{[d]} \) in the ideal world). Nevertheless, we notice that the intersecting elements in \( I_{X, new} \) could only come from either \( Y_d \) or \( I_{Y, old} \), both of which are relatively small sets and known to \( P_1 \). Therefore, we can let \( P_1 \) learn \( I_{X, new} \) by running a PSI with \( P_1 \) on the two sets \( X_d \) and \( Y_{[d]} \cup I_{Y, old} \). In this PSI protocol, \( P_1 \) needs to add dummy elements to hide the size of \( Y_{[d]} \cup I_{Y, old} \), but the set size is at most \( 2N_d \), hence the PSI is efficient in both computation and communication. The full protocol is described in Figure 3.

**4.2 Correctness, Efficiency, and Security**

**Correctness.** If both parties follow the protocol honestly, at the end of Day \( d \), we will have the following guarantees with all but negligible probability:

\(- I_d = X_{[d]} \cap Y_{[d]} \)

\[1\] Note that \( I_{Y, old} \) is defined as \( X_{d} \cap (Y_{[d-1]} \setminus I_{d-1}) \). Since \( X_{d} \) and \( I_{d-1} \) are disjoint, it holds that \( I_{Y, old} = X_{d} \cap Y_{[d-1]} \).
Initialization:

\( P_0 \) samples \( k_0 \leftarrow \mathbb{Z}_q \) and sets \( X_{\text{old}} := \emptyset, H_X := \emptyset, I_0 := \emptyset \).
\( P_1 \) samples \( k_1 \leftarrow \mathbb{Z}_q \) and sets \( Y_{\text{old}} := \emptyset, H_Y := \emptyset, I_0 := \emptyset \).

**Day \( d \)** Party \( P_0 \) inputs a set \( X_d \) of size \( N_d \); party \( P_1 \) inputs a set \( Y_d \) of size \( N_d \).

1. \( P_0 \) learns \( I_{X_{\text{old}}} = X_{\text{old}} \cap Y_d \):
   - \( P_1 \) computes \( H(Y_{\text{old}}) \) and sends to \( P_0 \).
   - On receiving \( H(Y_{\text{old}}) \), \( P_0 \) raises each element to the power \( k_0 \) to obtain \( H(Y_{\text{old}})^{k_0} \) and compares with \( H_X \) (which equals to \( H(X_{\text{old}})^{k_0} \)) to learn \( I_{X_{\text{old}}} = X_{\text{old}} \cap Y_d \).
2. Symmetrically, \( P_1 \) learns \( I_{Y_{\text{old}}} = Y_{\text{old}} \cap X_d \).
3. Both parties learn the updated intersection:
   - \( P_1 \) lets \( \hat{Y}_d := Y_d \cup I_{Y_{\text{old}}} \cup D_Y \) where \( D_Y \) consists of dummy random elements so that \(|\hat{Y}_d| = 2N_d|\).
   - \( P_0 \) and \( P_1 \) run a PSI protocol for \( \mathcal{F}_{\text{PSI}} \) where \( P_0 \)’s input set is \( X_d \) and \( P_1 \)’s input set is \( \hat{Y}_d \), from which only \( P_0 \) learns the output \( I_{X_{\text{new}}} \).
   - \( P_0 \) computes \( I_{\text{update}} := I_{X_{\text{new}}} \cup I_{X_{\text{old}}} \) and sends it to \( P_1 \).
   - Both parties compute \( I_d := I_{d-1} \cup I_{\text{update}} \) and output \( I_d \) for Day \( d \).
4. \( P_0 \) updates \( X_{\text{old}} \) and \( H_X \):
   - \( P_0 \) does the following:
     - Let \( X'_d := X_d \setminus I_{\text{update}} \) and \( \widetilde{X}_d := X'_d \cup D_X \) where \( D_X \) consists of dummy random elements so that \(|\widetilde{X}_d| = N_d| \).
     - Sample a uniform random \( \alpha \) from \( \mathbb{Z}_q \).
     - Compute \( H(\widetilde{X}_d)^{k_0\alpha} \) and send to \( P_1 \).
   - On receiving \( H(\widetilde{X}_d)^{k_0\alpha} \), \( P_1 \) raises each element to the power \( \alpha^{-1} \) to obtain \( H(\widetilde{X}_d)^{k_0\alpha} \), from which derive \( H(\widetilde{X}_d)^{k_0\alpha} \).
   - Update \( X_{\text{old}} := \left( X_{\text{old}} \setminus I_{X_{\text{old}}} \right) \cup X'_d \) and \( H_X := H(X \setminus H(I_{Y_{\text{old}}})^{k_0\alpha}) \cup H(X_d)^{k_0\alpha} \).
5. Symmetrically, \( P_1 \) updates \( Y_{\text{old}} := Y_{\text{old}} \setminus I_{Y_{\text{old}}} \cup (Y_d \setminus I_{\text{update}}) \) and \( H_Y \).

![Fig. 3. Two-sided UPSI with addition protocol II_{\text{PSI-add-two}}.](image-url)

- \( X_{\text{old}} := X_{[d]} \setminus I_d \) and \( H_X := H(X_{\text{old}})^{k_0\alpha} \)
- \( Y_{\text{old}} := Y_{[d]} \setminus I_d \) and \( H_Y := H(Y_{\text{old}})^{k_0\alpha} \)

We prove this by induction in Appendix C.1.

**Complexity.** On Day \( d \), both parties perform \( O(N_d) \) exponentiations and a PSI protocol with set sizes \( O(N_d) \). The PSI protocol has both computational and communication complexity \( O(N_d) \). Hence the total computational and communication complexity are both \( O(N_d) \) and independent of the total set size of each party.

**Security.** We defer the security proof to Appendix C.2, and only state the theorem below.

**Theorem 4.1.** Assumption the Decisional Diffie-Hellman (DDH) assumption holds for the group \( G \) and \( H(\cdot) \) is modeled as a random oracle, the protocol \( \text{II}_{\text{PSI-add-two}} \) presented in Figure 3 securely realizes the ideal functionality \( \mathcal{F}_{\text{PSI-add-two}} \) (defined in Figure 1) in the \( \mathcal{F}_{\text{PSI}} \)-hybrid model against semi-honest adversaries.

### 5 One-Sided UPSI with Addition

In this section, we present a one-sided UPSI with addition protocol satisfying Definition 3.2, where only one party \( P_1 \) receives the output on each day.

#### 5.1 Construction

**Notation.** Let \( \lambda \) be the computational security parameter and \( \sigma \) be the statistical security parameter. Let \( G \) be a group of prime order \( q \) with generator \( g \). Let \( H_1 : \{0, 1\}^* \rightarrow G \) be a hash function and \( H_2 : \{0, 1\}^* \rightarrow \{0, 1\}^\lambda \) be another hash function. Let \( \text{AHE} = (\text{KeyGen}, \text{Enc}, \text{Dec}) \) be an additively homomorphic encryption scheme where the message space is a field \( \mathbb{F}_p \). For a set \( X \subseteq \{0, 1\}^\ell \), we denote \( H_1(X) := \{H_1(x) | x \in X\} \) and \( H_2(X)^k := \{H_2(x)^k | x \in X\} \). We denote \( \text{Enc}_{\text{ph}}(X) \) as \( \{\text{Enc}_{\text{ph}}(x) | x \in X\} \).

Let \( \text{LSI}(n) \) denote the position of the least significant one in the binary representation of \( n \). In other words, if \( n = \sum_{i=0}^{k} b_i \cdot 2^i \), then \( \text{LSI}(n) := \min\{i : b_i = 1\} \).

For example, \( \text{LSI}(7) = 0 \) and \( \text{LSI}(12) = 2 \). For a string \( s \in \{0, 1\}^\ell \), let \( s_{[1..k]} \) (where \( 1 \leq k \leq \ell \)) be the number whose binary representation is the leading \( k \) bits of \( s \).
For example, for $s = 010110$, $s_{[1..4]} = (0101)_2 = 5$. In addition, we let $s_{[1..k]} = 0$ for $k = 0$.

Let a node denote a collection of at most $4\sigma$ elements (or encrypted elements). For each $i \in \mathbb{N}$, let $D_i$ denote an array of $2^i$ nodes on the $P_1$ side and let $D_i[j]$ (where $j \in \{0,1,\ldots,2^i-1\}$) be the $j$-th node in $D_i$. Similarly, let $\bar{D}_i$ denote an array of $2^i$ nodes (containing encrypted elements) on the $P_0$ side and let $\bar{D}_i[j]$ be the $j$-th node in $\bar{D}_i$.

**Construction Overview.** For simplicity, we assume $N_d = \sigma$ on each Day $d$. We discuss how to extend our protocol for $N_d \neq \sigma$ in Appendix E. Without loss of generality, we assume all the set elements are in the field $F_p$, namely in the message space of AHE. In case they are not, we can first apply a hash function $H : \{0,1\}^* \rightarrow F_p$ on all the elements.

To learn the updated intersection $I_d$ on each Day $d$, party $P_0$ only needs to learn the update set $I_{\text{update}} = I_d \setminus I_{d-1}$. Similar to the previous protocol $\Pi_{\text{UPS1-add-two}}$ (see Figure 3), $I_{\text{update}}$ can be split into two disjoint sets, $I_{X,\text{old}} = X_{\text{old}} \cap Y_d$ and $I_{X,\text{new}} = X_{\text{new}} \cap Y_d$ (both can be inferred from the output in the ideal world). We first use the same approach as in the protocol $\Pi_{\text{UPS1-add-two}}$ to let $P_0$ learn $I_{X,\text{old}}$. Next we describe how to let $P_0$ learn $I_{X,\text{new}}$ without leaking any information to $P_1$.

At a high level, $P_1$ stores all his elements in an encrypted form on $P_0$’s storage in such a way that: (a) $P_1$ can efficiently and data-obliviously insert new elements to the storage, and (b) $P_0$ can efficiently query if her element $x$ is in the storage. We construct a binary tree structure to achieve the data obliviousness, efficient data insertion, and efficient data query reminiscent of constructions for oblivious ram (ORAM) $[\text{SvDS}^{+18}]$. In particular, $P_1$ stores all his elements in a binary tree, which can be updated efficiently when new elements are added to his set. On each day, $P_1$ updates his tree structure and then sends the corresponding updated encryptions to $P_0$, which allows her to update the encrypted tree. To query if $P_0$’s element $x$ is in the encrypted tree, $P_0$ will locate a small set of elements that could possibly contain $x$. By utilizing additively homomorphic encryption, $P_0$ is able to learn whether $x$ is among these elements (with $P_1$’s help) without leaking any information about $x$ to $P_1$.

The binary tree structure works as follows. Initially, the tree is empty. Each node of the tree has a maximum capacity $O(\sigma)$. On each day when there are new elements added to $P_1$’s set, $P_1$ will insert the new elements into the tree. Intuitively speaking, $P_1$ starts by adding the new elements to the root of the tree. If the root is full (i.e., reaches the maximum capacity), then $P_1$ pushes the elements in the root along with the new elements to the second level of the tree. If the second level has any full node, then $P_1$ pushes all the elements down to the third level. This process continues – if the first $L$ levels of the tree contains any full node, then $P_1$ pushes all the elements in the first $L$ levels, along with the new elements, to the $(L + 1)$-st level of the tree, and then empties the first $L$ levels. For a particular level, an el-
mement $y$ is put into a (pseudo-)random node of that level, determined by the output of a hash function $H_2(y)$.

To make the above process data oblivious to $P_0$, $P_1$ should not wait until exactly when a node is full because that may leak information about $P_1$’s elements. Instead, “pushing” happens in a predetermined way that only depends on $P_1$’s set sizes (which is public to $P_0$ as well) with the guarantee that no node will reach full capacity except with negligible probability. As an illustration, Figure 4 shows the pushing process on Day $d = 20$, where $P_1$ pushes all the elements in the first two levels of the tree along with the new elements to the third level.

After $P_1$ updates his local tree structure, he pads every updated node to the maximum capacity using dummy elements and then sends them in an encrypted form to $P_0$, which allows her to update the encrypted tree structure. Next, when $P_0$ wishes to query if an element $x$ is in the tree, for each $x \in X_d$, she can first locate a root-to-leaf path of the tree that could possibly contain $x$ (by computing $H_2(x)$). Then, by utilizing additively homomorphic encryption and with the help of $P_1$, $P_0$ can learn whether $x$ is contained in any node of the path without learning any more information and without leaking $x$ to $P_1$. The full protocol is described in Figure 5.

5.2 Correctness, Security, and Extension

**Correctness.** We can prove correctness by induction over days. One crucial step is to argue that the protocol aborts in Step 3 with negligible probability. The intuition is that if we throw $N = \text{Poly}(\sigma)$ balls into $N \sigma$ bins uniformly at random, then the probability that any bin exceeds the size of $4\sigma$ is negligible. We defer the formal correctness proof to Appendix D.1.

**Security.** We defer the security proof to Appendix D.2, and only state the theorem below.

**Theorem 5.1.** Given an additively homomorphic encryption scheme $\text{AHE}$, assuming that the Decisional Diffie-Hellman (DDH) assumption holds for the group $G$, and that $H_1, H_2$ are modeled as random oracles, the protocol $\Pi_{\text{UPSI-add-one}}$ presented in Figure 5 securely realizes the ideal functionality $F_{\text{UPSI-add-one}}$ (defined in Figure 1) against semi-honest adversaries.

**Extension.** We can extend our protocol to the general setting when the number of elements added by both parties on any day $N_d \neq \sigma$, which we discuss in detail in Appendix E.

5.3 Optimizations

We now discuss some optimizations to improve the concrete efficiency of the protocol.

**Cuckoo Hashing.** In Step 3c, for each element $y \in S$, instead of adding $y$ to the (end of) node $D_{L[j]}$, we store elements in each node using Cuckoo hashing [PR04]. In more detail, to implement Cuckoo hashing, as discussed in Section 2, we pick three hash functions $\text{CuH}_1, \text{CuH}_2, \text{CuH}_3$. Each node of the tree $D_{L[j]}$ is represented as a collection of $b$ bins. We also have a small stash associated with each node. Now, each $y$ is inserted into one of these $b$ bins (or the stash) at any given node depending on the contents of bins $\text{CuH}_1(y), \text{CuH}_2(y), \text{CuH}_3(y)$. Similarly, we also include the elements from the stash when defining $S$ and setting $D_{I[j]} = \emptyset$ in Step 3.

The advantage is that, in Step 5, for each $x \in X_d$, $i \in \{0, \ldots, \text{max}L\}$, non-empty node $D_{I[j]}$ (where $j = H_2(x) \bmod (L \cdot 2\sigma)$), instead of comparing $x$ with each of the $4\sigma$ elements in the node, $P_0$ needs to compare with only the three elements at bins $\text{CuH}_1(x), \text{CuH}_2(x), \text{CuH}_3(x)$ and those in the associated stash. This significantly reduces the communication and computation cost.

In our implementation (Section 7.3), we set the Cuckoo hashing parameters according to the work of Pinkas et al. [PSSZ15]. In particular, we set the number of bins $b = 5\sigma$ and stash size to be a small constant.

**El Gamal Encryption.** We instantiate the additively homomorphic encryption scheme using the exponential variant of the El Gamal scheme [Gam84] to take advantage of the efficient elliptic curve operations. Recall that in this scheme, $\text{Enc}(m) = (g^r, h^r \cdot g^m)$ where the public key consists of a generator $g$ and group element $h = g^x$. The secret key is $x$. In our protocol, let $pk_0 = (g, h_0), pk_1 = (g, h_1), sk_0 = x_0, sk_1 = x_1$ — that is, both parties use the same group and generator $g$.

First, in Step 5c, instead of decrypting $ct_0$, entirely, $P_0$ can just check if the decryption is $0$ more efficiently. In particular, given $ct_r = (a, b)$, $P_0$ can check if $r = 0$ by checking if $b = a^{r}$. Similarly, in Step 5(b)i, given $ct_j = (a, b)$, instead of decrypting to get $\beta$ and then re-encrypting using $pk_0, P_1$ can compute $\text{Enc}_{pk_0}(\beta)$ directly as $(g^s, h_0^s \cdot b_{s/\sigma})$ where $s$ is randomly sampled.

**Reducing Number of Ciphertexts in $C_0$.** We can reduce communication by modifying Step 5(a)i to allow

---

2 Decryption of exponential variant of El Gamal requires computing the discrete logarithm of a group element which would only work for a small message space and be expensive.
Initialization:
1. $P_0$ samples $k_0 \leftarrow \mathbb{Z}_q$ and sets $X_{\text{old}} := \emptyset$, $H_X = \emptyset$, $I_0 := \emptyset$, and $\mathcal{D}_i[j] := \emptyset$ for all $i \in \mathbb{N}$ and all $j \in \{0, 1, \ldots, 2^i - 1\}$.
2. $P_1$ samples $k_1 \leftarrow \mathbb{Z}_q$ and sets $\mathcal{D}_i[j] := \emptyset$ for all $i \in \mathbb{N}$ and all $j \in \{0, 1, \ldots, 2^i - 1\}$.
   Both parties set $\max L := 0$.
3. $P_0$ generates $(pk_0, sk_0) \leftarrow \text{KeyGen}(1^\lambda)$ and sends $pk_0$ to $P_1$.
4. $P_1$ generates $(pk_1, sk_1) \leftarrow \text{KeyGen}(1^\lambda)$ and sends $pk_1$ to $P_0$.

Day $d$:
1. $P_0$ inputs set $X_d$ of size $\sigma$; $P_1$ inputs set $Y_d$ of size $\sigma$.
2. $P_1$ learns $I_{X, \text{old}} = X_{\text{old}} \cap Y_d$:
   (a) $P_1$ computes $H_1(Y_d \cdot k_1)$ and sends to $P_0$.
   (b) On receiving $H_1(Y_d \cdot k_1)$, $P_0$ raises each element by $k_0$ to obtain $H_1(Y_d \cdot k_0 \cdot k_1)$ and compares with $H_X$ (which equals $H_1(X_{\text{old}} \cdot k_0 \cdot k_1)$) to learn $I_{X, \text{old}} = X_{\text{old}} \cap Y_d$.
3. Both parties let $L := \text{LSI}(d)$ and $\max L := \max \{L, \max L\}$.
4. $P_1$ updates $D$ by doing the following:
   (a) Let $S := \left( \bigcup_{i=0}^{L-1} \bigcup_{j=0}^{2^i-1} \mathcal{D}_i[j] \right) \cup Y_d$.
   (b) For each $i \in \{0, 1, \ldots, L\}$ and for each $j \in \{0, 1, \ldots, 2^i - 1\}$, set $\mathcal{D}_i[j] := \emptyset$.
   (c) For each element $y \in S$, let $j := H_2(y) \in \{1, \ldots, L\}$ and add $y$ into the node $\mathcal{D}_L[j]$. If the size of $\mathcal{D}_L[j]$ exceeds $4\sigma$, then abort.
   (d) For each $j \in \{0, 1, \ldots, 2L - 1\}$, construct a node $\mathcal{D}_L[j]$ of size $4\sigma$ by padding $\mathcal{D}_L[j]$ with dummy random elements.
   Compute $\mathcal{D}_L[j] \gets \text{Enc}_{pk_1}(\mathcal{D}_L[j])$.
   (e) Send $\{\mathcal{D}_L[j]\}_{j \in \{0, 1, \ldots, 2L - 1\}}$ to $P_0$.
5. $P_0$ updates $D$ by doing the following:
   (a) For each $i \in \{0, 1, \ldots, L\}$ for each $j \in \{0, 1, \ldots, 2^i - 1\}$, set $\mathcal{D}_i[j] := \emptyset$.
   (b) For each $i \in \{0, 1, \ldots, 2L - 1\}$, set $\mathcal{D}_L[j] := \mathcal{D}_L[j]$.
6. $P_0$ learns $I_{X, \text{new}} = X_d \cap Y_d$: $P_0$ first sets $I_{X, \text{new}} := \emptyset$. Then for each $x \in X_d$:
   (a) $P_0$ does the following:
      i. Set $C_0 := \emptyset$. For each $i \in \{0, \ldots, \max L\}$, let $j := H_2(x) \in \{0, \ldots, L\}$; if $\mathcal{D}_i[j] \neq \emptyset$, then for each $ct \in \mathcal{D}_i[j]$:
         Sample $\alpha \leftarrow \mathbb{F}_p$, compute $\alpha^- \text{ct}_\alpha \leftarrow \text{Enc}_{pk_0}(\alpha)$ and $\text{ct}_\beta := \text{Enc}_{pk_0}(\alpha + \beta \cdot \text{ct})$, and send a pair $(\text{ct}_\alpha, \text{ct}_\beta)$ to $C_0$.
      ii. Send $C_0$ to $P_1$.
   (b) $P_1$ does the following:
      i. Set $C_1 := \emptyset$. For each pair $(\text{ct}_\alpha, \text{ct}_\beta) \in C_0$, sample $\gamma \leftarrow \mathbb{F}_p$, compute $\beta^- \text{ct}_\beta \leftarrow \text{Dec}_{sk_1}(\beta \cdot \text{ct})$, $\text{ct}_\gamma \leftarrow \gamma \cdot (\text{Enc}_{pk_0}(\beta) \oplus \text{ct}_\alpha)$ and add $\text{ct}_\gamma$ to $C_1$.
      ii. Send $C_1$ in a randomly permutated order to $P_0$.
   (c) $P_0$ does the following:
      For each $\text{ct}_\gamma \in C_1$, compute $r^- \text{Dec}_{sk_0}(\text{ct}_\gamma)$. Add $x$ to the set $I_{X, \text{new}}$ if $r = 0$.
7. $P_0$ outputs $I_d := I_{d-1} \cup I_{X, \text{old}} \cup I_{X, \text{new}}$ for Day $d$.
8. $P_0$ updates $X_{\text{old}}$ and $H_X$:
   (a) $P_0$ does the following:
      Let $X_d' := X_d \setminus I_d$ and construct $X_d'$ of size $\sigma$ by padding $X_d'$ with dummy random elements.
      Sample $\alpha \leftarrow \mathbb{Z}_q$, compute $H_1(X_d' \cdot k_0 \cdot k_1)$ and send to $P_1$.
   (b) $P_1$ raises each element in $H_1(X_d' \cdot k_0 \cdot k_1)$ to the power $k_1$ to obtain $H_1(X_d' \cdot k_0 \cdot k_1)$ and sends back to $P_0$.
   (c) $P_0$ raises each element in $H_1(X_d' \cdot k_0 \cdot k_1)$ to the power $\alpha^- 1$ to obtain $H_1(X_d' \cdot k_0 \cdot k_1)$, from which it derives $H_1(X_d')$.
   Then $P_0$ updates $X_{\text{old}} := \{X_{\text{old}} \setminus I_{X, \text{old}} \} \cup X_d'$ and $H_X := H_X \setminus H_1(I_{X, \text{old}})$ and $H_X := H_X \cup H_1(X_d')$.

Fig. 5. One-sided UPSI with addition protocol $\Pi_{\text{UPS1-add-one}}$.

$P_0$ to use the same $\text{ct}_\alpha$ across all the ciphertext tuples generated for a given $x \in X_d$. In more detail, we rewrite the step as:
- Sample $\alpha \leftarrow \mathbb{F}_p$. Compute $\text{ct}_\alpha \leftarrow \text{Enc}_{pk_0}(\alpha)$ and add $\text{ct}_\alpha$ to $C_0$.
- For each $i \in \{0, \ldots, \max L\}$, let $j := H_2(x) \in \{1, \ldots, L\}$; if $\mathcal{D}_i[j] \neq \emptyset$, then for each $ct \in \mathcal{D}_i[j]$; compute $ct_{\beta,r}$ as $(\text{Enc}_{pk_1}(\alpha) \oplus \beta \cdot \text{ct})$ where $\beta \leftarrow \mathbb{F}_p$ and $(\oplus, \circ, \circ)$ are homomorphic operations. That is, $\text{ct}_{\beta,r} = \text{Enc}_{pk_1}(\alpha + \beta \cdot (x - y))$ where $\text{ct} = \text{Enc}_{pk_1}(y)$.
- Add $\text{ct}_{\beta,r}$ to $C_0$.

This change does not leak any additional information to $P_1$ because, by assumption, since elements added by $P_1$ on any day are distinct, with all but negligible probability, $x = y$ for at most only one $y$ amongst the plaintexts encrypted to form ciphertexts $\{ct\}$ (the negligible probability error happens if $x$ equals any of the random
dummy elements too). For any $x \neq y$, $\beta_r \cdot (x - y)$ is statistically close to a uniform distribution since $\beta_r$ is picked uniformly at random and so, reveals no information about any $x$ to $P_1$. It is easy to observe that this optimization does not affect security against a corrupt $P_0$ as well while reducing the size of $C_0$ by half.

### 5.4 Efficiency

We now evaluate the communication and computational complexity of the protocol (after applying the optimizations). For simplicity, we analyze the case where $N_d = \sigma$ and discuss the case of $N_d \neq \sigma$ in Appendix E. Recall the notation Num1($n$) that denotes the number of 1’s in the binary representation of $n$. For any Day $d$, Num1($d$) is the number of levels of the tree that are non-empty. Let the stash size (a small constant) for any node in the tree be denoted by $s$ (which is a small constant). Over a period of $d$ days, the total number of elements in the input set of each party is $N = \sigma \cdot d$.

**Communication Complexity.** In Step 1, $P_1$ sends $\sigma$ group elements. In Step 3, $P_1$ sends $(2^L \cdot 5\sigma)$ ciphertexts, where $L = \text{LS1}(d)$. In Step 5, $P_0$ first sends $\sigma \cdot (1 + \text{Num1}(d) \cdot (s + 3))$ ciphertexts and $P_1$ responds back with $\sigma \cdot (\text{Num1}(d) \cdot (s + 3))$ ciphertexts. In Step 7, both parties send $\sigma$ group elements. Thus, the overall communication complexity is $O(\sigma \cdot (2^{\text{LS1}(d)} + \text{Num1}(d)))$ group elements. Now, the values of $\text{LS1}(d)$ and $\text{Num1}(d)$ differ on every day and so the communication cost is not the same on each day. We consider amortized cost over $2^k$ days of updates for $d \in \{2^k, 2^k + 1, \ldots, 2^{k+1} - 1\}$. The amortized $2^{\text{LS1}(d)}$ is $\frac{\sum_{d=2^k}^{2^{k+1}-1} 2^{\text{LS1}(d)}}{2^k} = \frac{2^k + \sum_{d=2^k}^{2^{k+1}-1} 2^{\text{LS1}(d)}}{2^k} = 1 + \frac{k}{2}$. The amortized $\text{Num1}(d)$ is $\frac{\sum_{d=2^k}^{2^{k+1}-1} \text{Num1}(d)}{2^k} = \frac{2^k + \sum_{d=2^k}^{2^{k+1}-1} \text{Num1}(d)}{2^k} = 1 + \frac{k}{2}$.

Thus, the amortized communication cost over $2^k$ days is $O(\sigma \cdot k)$. Since the total number of elements $N = \sigma \cdot d$, $k = O(\log N)$ and so the amortized communication cost is $O(\sigma \cdot \log N)$. In particular, it grows only logarithmically with the total number of elements.

**Computational Complexity.** First, we analyze the computation cost for $P_0$. In Step 1, $P_0$ performs $\sigma$ exponentiations. In Step 4, $P_0$ stores the $2^L$ nodes – this is inexpensive compared to exponentiations. In Step 5, $P_0$ generates $\sigma \cdot (1 + \text{Num1}(d) \cdot (s + 3))$ ciphertexts (and decrypting later to check for 0). In Step 7, $P_0$ does $2\sigma$ exponentiations. Hence $P_0$’s computation cost is $O(\sigma \cdot \text{Num1}(d))$.

Next, we analyze $P_1$’s cost. In Step 1, $P_1$ does $\sigma$ exponentiations. In Step 3, $P_1$ generates $(2^L \cdot 5\sigma)$ encryptions, where $L = \text{LS1}(d)$. In Step 5, $P_1$ performs $\sigma \cdot (1 + \text{Num1}(d) \cdot (s + 3))$ encryptions/homomorphic evaluations. In Step 7, $P_1$ does $\sigma$ exponentiations. So $P_1$’s computation cost is $O(\sigma \cdot (2^{\text{LS1}(d)} + \text{Num1}(d)))$.

As analyzed above, the amortized computation cost is $O(\sigma \cdot k)$ over $2^k$ days of updates for $d \in \{2^k, 2^k + 1, \ldots, 2^{k+1} - 1\}$. Since the total number of elements $N = \sigma \cdot d$, we have $k = O(\log N)$ and the amortized computation cost is $O(\sigma \cdot \log N)$, which grows only logarithmically with the total number of elements.

### 6 UPSI with Weak Deletion

In this section, we describe an updatable PSI protocol satisfying Definition 3.3. That is, besides inserting new elements to their sets each day, the protocol allows both parties to delete data that was added $t$ days ago and compute the intersection privately on these new updated sets. In particular, the output is the union of the intersection of each party’s new elements with the other party’s updated set comprising elements over the last $t$ days. Our protocol allows both parties to learn the output at the end of each day and is based on oblivious transfer (OT) and correlation robust hash functions.

We first introduce the notion of sender-streaming PSI and then use that to build our updatable PSI protocol with weak deletion.

#### 6.1 Sender-Streaming PSI

Consider two parties - a sender $S$ and a receiver $R$ who wish to engage in a one-sided PSI protocol to allow $R$ to learn the intersection without revealing anything else. However, unlike the typical PSI setting, only $R$ knows its entire input set $Y$ at the beginning while the sender only knows a subset $X_0$. An upper bound $\text{Max}$ on the maximum number of elements in the sender’s set is part of the public parameters as are the sizes $|Y|, |X_0|$. At this point, the receiver learns $(X_0 \cap Y)$. Subsequently, the sender learns more of its input in a streaming manner and the two parties interact to allow the receiver to learn the intersection of its input set with the new streamed sender input. That is, on receiving an streaming input $X_i$, the two parties engage in a protocol that allows the receiver to learn $(X_i \cap Y)$. We formalize this notion as a special case of secure two-party computation with a reactive functionality defined in Figure 6.

Let $X[i] = \{X_0, \ldots, X_i\}$ be the inputs of $S$ over $i$ streams and $Y$ be the input of $R$. Let View$^R_{L_1}(X[i], Y, \text{Max})$, View$^R_{L_2}(X[i], Y, \text{Max})$ be the views of $S$ and $R$, respectively, in the protocol $II$ at the end.
Initialization:
- Inputs:
  - $S$ inputs a set $X_0$ where each element is from $\{0,1\}^*$.
  - $R$ inputs a set $Y$ where each element is from $\{0,1\}^*$.
  - The set sizes $|X_0|, |Y|$ and upper bound $\text{Max}$ are public and known to both parties.
- Output:
  - The ideal functionality sets $X = X_0$. Then, it computes and sends $X_0 \cap Y$ to $R$.

Stream $i$:
- Inputs:
  - $S$ inputs a set $X_i$ where each element is from $\{0,1\}^*$ and $X_i \cap X = \emptyset$. The stream size $|X_i|$ is public and known to $R$.
- Output:
  - The ideal functionality sets $X = X \cup X_i$. Then, if $|X| \leq \text{Max}$, it computes and sends $I_i = X_i \cap Y$ to $R$. Else, sends $\perp$.

Fig. 6. Ideal functionalities $F_{\text{SSPSI}}$ for sender-streaming PSI.

of $i$ streams and let $\text{Out}^{\Pi,i}(X_i, Y, \text{Max})$ be the outputs of $R$ at the end of $i$ streams. Let $f(X_i, Y, \text{Max}) := \{I_0, \ldots, I_i\}$ be the outputs of the ideal functionality in the $i$ streams.

Definition 6.1. (Sender-Streaming PSI.) A protocol $\Pi$ is semi-honest secure with respect to ideal functionality $F_{\text{SSPSI}}$ if there exists PPT simulators $\text{Sim}_S$ and $\text{Sim}_R$ such that for any $i \in \mathbb{N}$, any inputs $(X_i, Y)$ and any upper bound $\text{Max}$,

1. View$_R^{\Pi,i}(X_i, Y, \text{Max}) \approx (\text{Sim}_R(1^\lambda, Y, \{X_j\}_{j \in [i]}, \text{Max}, f(X_i, Y, \text{Max})),
2. View$_S^{\Pi,i}(X_i, Y, \text{Max}), \text{Out}^{\Pi,i}(X_i, Y, \text{Max}) \approx (\text{Sim}_S(1^\lambda, X_i, Y, \text{Max}), f(X_i, Y, \text{Max})).

Instantiations. We notice that the PSI protocols of Kolesnikov et al. [KKRT16], Pinkas et al. [PRTY19], Chase and Miao [CM20] immediately satisfy Definition 6.1. We state the lemma below and defer the discussion to Appendix F.

Lemma 6.2. Assuming semi-honest OT and correlation robust hash functions, the PSI protocols of [KKRT16, PRTY19, CM20] all securely realize the ideal functionality $F_{\text{SSPSI}}$ against semi-honest adversaries.

6.2 Construction

Notation. On each Day $d$, let $X_d$ be the elements added to $P_0$’s set and $Y_d$ be added to $P_1$’s set where $|X_d| = |Y_d| = N_d$. For any $j$, we will initialize $X_j = Y_j = \emptyset$ if they have not yet been defined (or $j \leq 0$). Further, for any $d$, let $\text{Max}_d \geq (2 \cdot N_d + \sum_{j=d+1}^{d+t-1} N_j)$. We assume that $\text{Max}_d$ is known at the start of Day $d$ - that is, on any day, both parties know an upper bound on the number of elements they can add over the next $(t-1)$ days.

Since we invoke several instances of $F_{\text{SSPSI}}$, we introduce additional notation to identify the sender of $F_{\text{SSPSI}}$ and on which day of the UPSI protocol the functionality was first invoked. Let $F_{\text{SSPSI}}^{(P_0, d)}$ indicate that $P_0$ is the sender of the SS-PSI protocol, $P_1$ is the receiver and the functionality was first invoked on Day $d$.

Construction Overview. We focus on how $P_0$ computes the output - the final protocol is symmetric to allow $P_1$ to compute the output as well. On any Day $d$, observe that the output $I_d$ can be split into two disjoint sets: (i) $I_{d,0} = (X_{d-1} \setminus X_{d-1}) \cap Y_d$ and (ii) $I_{d,1} = X_d \cap (Y_d \setminus Y_{d-1})$. Then, $I_d = I_{d,0} \cup I_{d,1}$ (each of which can be inferred from the output in the ideal world). Note that $X_d \cap Y_d$ is included in $I_{d,1}$ and not $I_{d,0}$.

To compute $I_{d,0}$, note that $I_{d,0} = (X_{d-t+1} \cap Y_d) \cup \ldots \cup (X_{d-1} \cap Y_d)$, where $(X_j \cap Y_d)$ (for all $j \in \{d-t+1, \ldots, d\}$) can be inferred from the output in the ideal world. Our idea is to use the sender-streaming PSI ($F_{\text{SSPSI}}$) initiated on earlier days to let $P_0$ learn $(X_j \cap Y_d)$. In more detail, on each of the $(t-1)$ previous days, invoke $F_{\text{SSPSI}}^{(P_0, j)}$ with $P_0$ as receiver using input $X_j$ (on Day $j$) and $P_1$ as sender. The upper bound for the sender’s set size is discussed later. Then, on Day $d$, $P_1$’s streamed input for each of these instances is $Y_d$ which allows $P_0$ to learn $(X_j \cap Y_d)$. The same mechanism can be employed symmetrically for $P_1$ to learn $I_{d,1} = X_d \cap (Y_{d-1} \setminus Y_{d-1})$.

Next, to compute $I_{d,\beta}$, the idea is to use a new instance $F_{\text{SSPSI}}^{(P_0, d)}$ on Day $d$ with $P_0$ as the receiver using input $X_d$ and $P_1$ as the sender. From the above paragraph, observe that this instance of $F_{\text{SSPSI}}$ is also used to compute terms of $I_{d,0}$ over the following $(t-1)$ days. Now, since the goal is to compute $I_{d,\beta} = X_d \cap (Y_d \setminus Y_{d-1})$, sender $P_1$’s input in its initial stream should be $(Y_d \setminus Y_{d-1})$ whose size is $\sum_{j=d-t+1}^{d-1} N_j$. Nonetheless, this can be improved. Observe that $I_{d,\beta} = (X_d \cap Y_d) \cup (X_d \cap (Y_{d-1} \setminus Y_{d-1})) = X_d \cap (Y_d \cup I_{d,1})$. Thus, sender $P_1$’s input to $F_{\text{SSPSI}}^{(P_0, d)}$ can be just $(Y_d \cup I_{d,1})$. Since $|I_{d,1}| \leq |N_d|$, size of $P_1$’s input is at most $(2 \cdot N_d)$. $P_1$ uses dummy elements to pad the size to be exactly $2 \cdot N_d$ to not leak more information about $I_{d,1}$ to $P_0$. Once again, $P_1$ can similarly learn $I_{d,\beta} = Y_d \cap (X_d \setminus X_{d-t})$.

Finally, the missing component is an upper bound on sender $P_1$’s entire input in $F_{\text{SSPSI}}^{(P_0, d)}$ initiated on Day $d$.
Recall that to compute $I_{0, \alpha}$, for each of the next $(t-1)$ days, $P_1$ uses streamed input $Y_j$ on Day $j$. Hence the upper bound is $(2 \cdot N_d + \sum_{j=d+1}^{d+t-1} N_j)$. The protocol is described in Figure 7.

### 6.3 Correctness, Security, and Efficiency

**Correctness.** If both parties follow the protocol honestly, at the end of Day $d$, we will have the guarantee that with all but negligible probability, $I_d = ((X_d \setminus X_{d-1}) \cap Y_d) \cup ((Y_d \setminus Y_{d-1}) \cap X_d)$. We prove by induction in Appendix G.1.

**Security.** We defer the security proof to Appendix G.2, and only state the theorem below.

**Theorem 6.3.** The protocol $\Pi_{\text{UPSI-del}}$ presented in Figure 7 securely realizes the ideal functionality $F_{\text{UPSI-del}}$ (defined in Figure 2) in the $\mathcal{F}_{\text{SSPSI}}$-hybrid model against semi-honest adversaries.

Instantiating $\mathcal{F}_{\text{SSPSI}}$ with the protocol of Kolesnikov et al. [KKRT16] or Pinkas et al. [PRTY19] or Chase and Miao [CM20], all of which are based on semi-honest OT and correlation robust hash functions (Lemma 6.2), we get the following corollary:

**Corollary 6.4.** Assuming semi-honest OT and correlation robust hash functions, the protocol $\Pi_{\text{UPSI-del}}$ presented in Figure 7 securely realizes the ideal functionality $F_{\text{UPSI-del}}$ (defined in Figure 2) against semi-honest adversaries.

**Computational and Communication Complexity.** On Day $d$, $\mathcal{F}_{\text{SSPSI}}$ is invoked with a new stream 2·$(t-1)$ times with size of new streamed set as $N_d$. The total computational complexity in this step is $O(N_d \cdot \sigma \cdot t)$ and the communication complexity is $O(N_d \cdot \lambda \cdot t)$ bits. Besides, two new invocations of $\mathcal{F}_{\text{SSPSI}}$ (the initialization phase) occur where the receiver’s set size is $N_d$ and the sender’s set size is $2 \cdot N_d$. The computational complexity in this step is $O(N_d \cdot \lambda)$ and communication complexity is $O(N_d \cdot \lambda)$ bits. Thus, the total computational complexity is $O(N_d \cdot \lambda)$ and the total communication complexity is $O(N_d \cdot (\sigma \cdot t + \lambda))$ bits.

As opposed to our protocols for PSI with addition which achieve better asymptotic complexity than a fresh PSI protocol, our weak deletion protocol $\Pi_{\text{UPSI-del}}$ appears more as an observation on the existing PSI protocols (in particular, their sender-streaming property). In fact, the weak deletion protocol $\Pi_{\text{UPSI-del}}$ has the same asymptotic complexity as a fresh PSI, but achieves a better concrete efficiency by smaller constant factors.

The protocol is a generic construction from sender-streaming PSI and its performance depends on the underlying sender-streaming PSI protocol.

### 7 Experimental Results

We implement our two-sided and one-sided UPSI with addition protocols ($\Pi_{\text{UPSI-add-two}}$ and $\Pi_{\text{UPSI-add-one}}$) in C++ and report their performance in this section.

#### 7.1 Implementation Details

We set the computational security parameter to $\lambda = 128$ and statistical security parameter to $\sigma = 40$. We use the CryptoTools library [Rin] for our underlying cryptographic primitives. In particular, we use the Boost library [Boo] for networking, the Relic library [AGM+] for the instantiation of elliptic curves, and SHA256 from OpenSSL [Ope] for the hash functions.

We compare our UPSI with addition protocols with the state-of-the-art OT extension based semi-honest PSI protocols which are optimized for different network settings:

- KKRT16 [KKRT16]: computation-optimized and works best in the setting of LAN networks.
- SpOT-Light [PRTY19]: communication-optimized and works best in networks with low bandwidth. They have two variants of the protocol, a speed-optimized variant (spot-fast) and a communication-optimized variant (spot-low). We compare our protocols with both variants.
- CM20 [CM20]: balanced between computation and communication, and works best in networks with moderate bandwidth (e.g., 30 – 100 Mbps).

We run all the experiments between two Amazon AWS virtual machines with Intel(R) Xeon(R) 3.0 GHz CPU and 32 GB RAM, which communicate over a LAN network. We simulate the WAN connection using the Linux tc command, where the RTT latency is set to be 80 ms and we test on various network bandwidths. All of our experiments use a single thread for each party.

**Setting.** To demonstrate the updatable property, we consider the following setting: each party initially holds an empty set. Then, on every new Day $d$, both parties add a new set of size $N_d$ to their existing sets and wish to learn the updated set intersection. We repeat this process over a period of several days ($\frac{N_d}{N_d}$) till the total set size of each party is $N$. We compare the amortized (over the total number of days) communication cost and running time of our protocol with the prior PSI protocols [KKRT16, PRTY19, CM20], where, on any Day $d$,
Day 1: $P_0$ has input set $X_1$ and $P_1$ has input set $Y_1$. The protocol works as follows:

1. Invoke $F^{P_1}_{\text{SSPSI}}$ with $P_1$ as the receiver with input $X_1$, $P_1$ as the sender with initial input $Y_1$ and upper bound $\text{Max}_1$. $P_0$ learns output $I_1 = (X_1 \cap Y_1)$.
2. Invoke $F^{P_0}_{\text{SSPSI}}$ with $P_0$ as the receiver with input $Y_1$, $P_0$ as the sender with initial input $X_1$ and upper bound $\text{Max}_1$. $P_1$ learns output $I_1 = (X_1 \cap Y_1)$.

Day $d$: $P_0$ has new input set $X_d$ and $P_1$ has new input set $Y_d$. $P_0$’s and $P_1$’s input sets over the last $t$ days are $(X_{d-t+1}, \ldots, X_{d-1}, X_d)$ and $(Y_{d-t+1}, \ldots, Y_{d-1}, Y_d)$ respectively. The protocol works as follows:

1. $I_{0,\alpha} = \bigcup_{j=1}^{d-t+1} (X_j \cap Y_d)$: For each $j > 0$, invoke $F^{P_{0,j}}_{\text{SSPSI}}$ with $P_{0,j}$’s new streamed input as $Y_d$. Receiver $P_0$ learns output $(X_j \cap Y_d)$.
2. $I_{1,\alpha} = \bigcup_{j=1}^{d-t+1} (Y_j \cap X_d)$: For each $j > 0$, invoke $F^{P_{0,j}}_{\text{SSPSI}}$ with $P_{0,j}$’s new streamed input as $X_d$. Receiver $P_1$ learns output $(Y_j \cap X_d)$.
3. $I_{0,\beta} = (X_d \cap \bigcup_{j=d-t+1}^d Y_j)^T$: $P_0$ computes this as follows:
   (a) Invoke $F^{P_{d,j}}_{\text{SSPSI}}$ with $P_d$ as the receiver with input $X_d$, $P_d$ as the sender with initial input $B$ and upper bound $\text{Max}_d$ where the set $B = Y_d \cup \bigcup_{j=d-t+1}^d Y_j \cap X_d \cup D_Y$ where $D_Y$ consists of dummy random elements so that $|B| = 2 \cdot N_d$.
   (b) $P_d$’s output is $(X_d \cap (\bigcup_{j=d-t+1}^d Y_j))$ since $(X_d \cap (\bigcup_{j=d-t+1}^d Y_j)) = (X_d \cap B)$.
4. $I_{1,\beta} = (Y_d \cap \bigcup_{j=d-t+1}^d X_j)^T$: $P_1$ computes this similar to the above as follows:
   (a) Invoke $F^{P_{d,j}}_{\text{SSPSI}}$ with $P_d$ as the receiver with input $Y_d$, $P_d$ as the sender with initial input $A$ and upper bound $\text{Max}_d$ where the set $A = X_d \cup \bigcup_{j=d-t+1}^d X_j \cap Y_d \cup D_X$ where $D_X$ consists of dummy random elements so that $|A| = 2 \cdot N_d$.
   (b) $P_d$’s output is $(Y_d \cap (\bigcup_{j=d-t+1}^d X_j))$ since $(Y_d \cap (\bigcup_{j=d-t+1}^d X_j)) = (Y_d \cap A)$.
5. Output computation:
   $P_0$ outputs $I_d = (I_{0,\alpha} \cup I_{0,\beta})$ and $P_1$ outputs $I_d = (I_{1,\alpha} \cup I_{1,\beta})$.

Fig. 7. Updatable PSI protocol with weak deletion $\Pi_{\text{UPSI-del}}$.

the two parties run a fresh PSI on their updated sets to learn the updated intersection.

### 7.2 Two-Sided UPSI with Addition

We implement the two-sided UPSI with addition protocol $\Pi_{\text{UPSI-add-two}}$ presented in Section 4, where the PSI protocol in Step 3b is instantiated with a DDH-based PSI [Mea86, HHF99]. A detailed comparison for $N = 2^{16} - 2^{22}$ and $N_d = 2^8 - 2^{12}$ is presented in Table 2. Note that for the PSI protocols [KKRT16, PRTY19, CM20], we only report for $N_d = 2^8$ because both their communication and running time are dominated by $N$ (which is much larger than $N_d$) and do not differ much for other $N_d$ values.

#### Communication Improvement

The communication cost of our protocol on any day is proportional only to the update size $N_d$ and independent of the size of the entire set (that grows gradually to $N$), whereas all the PSI protocols require communication to grow with the entire set. Therefore, our protocol beats all the PSI protocols in amortized communication by $7.5 - 13250 \times$ in the settings we consider (where $N \gg N_d$).

#### Computation Improvement

Similar to communication, our computational cost also grows only with $N_d$ while all the PSI protocols require computation to grow with the size of the entire set (that gradually grows to $N$). However, our protocol does not beat their computation in all the settings because all these PSI protocols only use OT extension [IKNP03, ALSZ13] along with symmetric cryptographic primitives (AES/hash functions), which are computationally very efficient, while our protocol requires public-key operations. As a result, our protocol is computationally more expensive for smaller values of $N$ but eventually beats all these protocols when $N$ is sufficiently large. In particular, for $N = 2^{22}$ and $N_d = 2^8$, our protocol beats [KKRT16] (the computationally most efficient protocol) by $2.6 \times$ in computation.

#### Overall Running Time

Generally speaking, our protocol has more advantages in the total running time when the network bandwidth is lower, the total set size $N$ is larger, and the update size $N_d$ is smaller. For example, if we focus on the setting $N = 2^{20}$, when $N_d = 2^8$, our protocol beats the best PSI protocol by $1.1 - 24.5 \times$ for network bandwidth between $5 - 200$ Mbps; when

Table 2. Amortized communication cost (in MB) and running time (in seconds) comparing our protocol $\Pi_{\text{UPSI}}$-add-two to [KKRT16], spot-fast and spot-low [PRTY19], and [CM20]. The LAN network has 20 Gbps bandwidth and 0.1 ms RTT latency. All the other network settings have 80 ms RTT. Cells with “—” denote settings where the programs run out of memory and those in orange indicate the fastest running time for that setting.

$N_d = 2^{10}$, our protocol beats the best PSI protocol by 1.1 – 7.6× for network bandwidth between 5 – 50 Mbps; when $N_d = 2^{12}$, our protocol beats the best PSI protocol by 2.1× for network bandwidth 5 Mbps. On the other hand, for the setting where $N = 2^{22}$, when $N_d = 2^8$, our protocol beats the best PSI protocol by 2.6 – 73.7× for all networks.

### 7.3 One-Sided UPSI with Addition

We implement the one-sided UPSI with addition protocol $\Pi_{\text{UPSI}}$-add-one presented in Section 5 with the optimizations mentioned in Section 5.3. We pick the Cuckoo hashing parameters according to Pinkas et al. [PSSZ15]. In Figure 5, we set the batch size for both parties (the number of elements added each day) to be $2^6 = 64$ instead of $\sigma$ (which is 40).\(^3\) To insert $n = 4 \cdot 2^6 = 2^8$ elements into the Cuckoo hash table, we set the number of bins as $1.2n = 308$ and stash size as 12. A detailed comparison for $N = 2^{16} – 2^{20}$ and $N_d = 2^6 – 2^{10}$ is presented in Table 3.\(^4\) For the PSI protocols [KKRT16, PRTY19, CM20], we only report for $N_d = 2^8$ as their amortized communication and run-

---

\(^3\) We use $2^6$ instead of 40 for two reasons: In the parameters from [PSSZ15], the stash size is available only for $n = 2^8$ and not lower numbers. Also, since we consider daily updates that are powers of 2, running batches of $2^6$ is more convenient than 40.

\(^4\) Unlike Table 2, we don’t include $N = 2^{22}$ as we ran out of memory for that case.

Table 3. Amortized communication cost (in MB) and running time (in seconds) comparing our protocol $\Pi_{\text{UPSI}}$ to KKRT16, spot-fast and spot-low [PRTY19], and CM20. The LAN network has 20 Gbps bandwidth and 0.1 ms RTT latency. All the other network settings have 80 ms RTT. Cells with “—” denote settings where the programs run out of memory and those in orange indicate the fastest running time for that setting.

We note that for $N = 2^{20}$ and $N_d = 2^6$, our protocol beats [PRTY19] by $3.1 - 28.3 \times$ in computation. Overall Running Time. Our protocol generally has more advantages in the total running time when the network bandwidth is lower, the total set size $N$ is larger, and the update size $N_d$ is smaller. For example, consider $N = 2^{20}$; when $N_d = 2^6$, our protocol beats the best PSI protocol by $1.8 - 30.5 \times$ for network bandwidth between 5 – 50 Mbps; when $N_d = 2^8$, our protocol beats the best PSI protocol by $3.9 \times$ for network bandwidth 5 Mbps; when $N_d = 2^{10}$, our protocol beats the best PSI protocol by $1.2 \times$ for network bandwidth 5 Mbps.

encryption scheme AHE = (KeyGen, Enc, Dec) over message space \( \mathcal{M} \) with correctness, CPA security, and linear homomorphism.

- \((pk, sk) \leftarrow \text{KeyGen}(1^\lambda)\)
- \(ct \leftarrow \text{Enc}_{pk}(m; r)\)
- \(m \perp \text{Dec}_{sk}(ct)\)
- Homomorphic addition: \(\text{Enc}_{pk}(m_1) \oplus \text{Enc}_{pk}(m_2) = \text{Enc}_{pk}(m_1 + m_2)\) for \(\forall m_1, m_2 \in \mathcal{M}\).
- Homomorphic multiplication with constant: \(c \odot \text{Enc}_{pk}(m) = \text{Enc}_{pk}(c \cdot m)\) for \(\forall c, m \in \mathcal{M}\).

We implicitly assume that each homomorphic evaluation is followed by a refresh operation, where the resulting ciphertext is added with an independently generated encryption of zero. This is required in our protocols to ensure that the randomness of the final ciphertext is independent of the randomness used in the original set of ciphertexts. For the popular additively homomorphic encryption schemes such as ElGamal encryption [Gam84] (based on DDH) and Paillier encryption [Pai99] (based on the Decisional Composite Residuosity assumption), a homomorphically evaluated ciphertext is statistically identical to a fresh ciphertext. We refer to [Gam84, Pai99] for formal definitions of correctness and CPA security.

**Decisional Diffie-Hellman (DDH) Assumption.** Let \(G\) be a cyclic multiplicative group of prime order \(q\) with generator \(g\). Let \(a, b, c\) be sampled uniformly at random from \(\mathbb{Z}_q\). The DDH assumption states that

\[
(g^a, g^b, g^{ab}) \approx (g^a, g^b, g^c).
\]

## B Weak Deletion Functionality

In this section, we discuss the choice of our definition for the weak deletion functionality. We consider an alternate, arguably more natural functionality for deletion where both parties compute the intersection of their datasets over the last \(t\) days - that is, delete data that was added more than \(t\) days ago and compute the intersection on their updated sets. We define this functionality \(\mathcal{F}_{\text{UPSI-de1-alt}}\) in Figure 9. We make two observations about \(\mathcal{F}_{\text{UPSI-de1-alt}}\) to explain why we instead choose to focus on \(\mathcal{F}_{\text{UPSI-de1}}\) in this work.

**Leakage from Ideal Functionality.** It turns out that \(\mathcal{F}_{\text{UPSI-de1-alt}}\) in fact leaks a lot more information over the course of several days than what immediately meets the eye from the functionality description. In particular, both parties actually learn \(X_i \cap Y_j\) for all \(|i - j| < t\). To see why, consider the sequence of \(t\) days start-
Initialization: $X := \emptyset, Y := \emptyset$.

Day $d$:
- **Public parameter:** The set size on Day $d$ is $N_d$.
- **Inputs:**
  - $P_0$ inputs a set $X_d$ of size $N_d$ where each element is from $\{0, 1\}^*$, and $X_d \cap X = \emptyset$.
  - $P_1$ inputs a set $Y_d$ of size $N_d$ where each element is from $\{0, 1\}^*$, and $Y_d \cap Y = \emptyset$.
- **Update:** On receiving the inputs from the two parties, the ideal functionality updates $X := (X \cup X_d) \setminus X_{d-1}$, $Y := (Y \cup Y_d) \setminus Y_{d-1}$ and computes $I_d = X \cap Y$. (If $d - t \leq 0$, then $X_{d-t} = Y_{d-t} = \emptyset$.)
- **Output:** The ideal functionality sends $I_d$ to both parties.

**Fig. 9.** Ideal func. $\mathcal{F}_{\text{UPSI-del-alt}}$ for UPSI with weak deletion.

On day $d$ and see what $P_1$ learns from the output on each day about $X_d$. On Day $d$, $P_0$ can learn $(X_d \setminus (Y_{d-1} \setminus Y_{d-1}))$ from $I_d$. On Day $(d + 1)$, $P_0$ can infer $(X_d \setminus (Y_{d+1} \setminus Y_{d+1}))$ from $I_{d+1}$. From both the above, $P_0$ can immediately deduce $(X_d \cap Y_{d+1})$ and $(X_d \cap Y_{d-1})$. Similarly, for each $i \in \{d+2, \ldots, d+t-1\}$, $P_0$ can learn $(X_d \cap Y_i)$ and $(X_d \cap Y_{i-1})$. Finally, notice that on Day $(d+t-1)$, $P_0$ learns $X_d \cap (Y_{d-1} \setminus Y_{d-1})$. From this and the intermediate results on each day, $P_0$ can also learn $X_d \cap Y_d$. Observe that this leakage does not occur in $\mathcal{F}_{\text{UPSI-del}}$.

**Stronger Functionality ($\mathcal{F}_{\text{UPSI-del-alt}} \Rightarrow \mathcal{F}_{\text{UPSI-del-alt}}$).**

We show that $\mathcal{F}_{\text{UPSI-del-alt}}$ can be realized given $\mathcal{F}_{\text{UPSI-del}}$. That is, any protocol achieving $\mathcal{F}_{\text{UPSI-del}}$ can be easily transformed to achieve $\mathcal{F}_{\text{UPSI-del-alt}}$. Intuitively, the idea is that given the output $I_{d-1}$ of $\mathcal{F}_{\text{UPSI-del-alt}}$ on Day $(d-1)$, to obtain the output on Day $d$, we essentially need to do two things: (i) Add to $I_{d-1}$ the contribution of the new inputs $X_d$ and $Y_d$.
(ii) Remove from $I_{d-1}$ the contribution of the deleted data $X_{d-1}$ and $Y_{d-1}$. Observe that (i) is exactly the output of $\mathcal{F}_{\text{UPSI-del}}$ on Day $d$. For (ii), from the output $I_{d-1}$ and its own inputs, $P_0$ can compute $A = X_{d-1} \cap (Y_{d-1} \setminus Y_{d-1})$ which is the contribution of $X_{d-1}$ to $I_{d-1}$. Similarly, $P_1$ can compute $Y_{d-1}$'s contribution $B = Y_{d-1} \cap (X_{d-1} \setminus X_{d-1})$. Then, they can simply exchange this information with each other in plaintext and this completes (ii). This exchange doesn’t leak extra any information because, from the output of the functionality, $I_{d-1} \setminus I_d$ is in fact $(A \cup B)$. From this, and the knowledge of $A$ that $P_0$ can compute locally, $P_0$ can automatically learn $B$ in the ideal world. Similarly for $P_1$. For completeness, we describe the protocol formally in Figure 10.

**Motivating Example for $\mathcal{F}_{\text{UPSI-del}}$.** Finally, our motivating example for studying updatable PSI with weak deletion also holds for $\mathcal{F}_{\text{UPSI-del}}$. In privacy-preserving contact tracing, consider the scenario where one party’s (server’s) input is the set of people who tested positive on that day, the other party’s (client’s) input is the set of people they interacted with on that day. The output on each day is the union of two parts: (a) people who tested positive in the last $t$ days intersecting with those clients met on that day, and (b) people who tested positive on that day intersecting with those clients met in the last $t$ days. Essentially, this captures whether client is at risk of having been infected.

**C. Proofs for $\Pi_{\text{UPSI-add-two}}$**

**C.1 Correctness Proof**

We prove the guarantees presented in Section 4.2 by induction.

**Base Case:** These guarantees hold on Day 0 since all the sets are initialized as empty sets.

**Induction Step:** Suppose the guarantees hold on Day $(d-1)$. Let $I_{d-1}, X_{d-1}^{(d-1)}, H_X^{(d-1)}, Y_{d-1}^{(d-1)}, H_Y^{(d-1)}$ be the sets at the end of Day $(d-1)$. Now we consider Day $d$ with new sets $X_d$ and $Y_d$. Let $I_d, X_d^{(d)}, H_X^{(d)}, Y_d^{(d)}, H_Y^{(d)}$ be the sets at the end of Day $d$. In Step 1, party $P_0$ learns $H(Y_d)^{k_{0i}}$, and takes the intersection with $H_X^{(d-1)}$ (which equals to $H(X_{d-1})^{k_{0i}}$). By the collision resistance of the hash function $H$, the intersection would result in $X_{old}^{(d-1)} \cap Y_d$ with all but negligible probability, namely $I_x_{old} = X_{old}^{(d-1)} \cap Y_d$. Symmetrically, $I_{y,old} = Y_{old}^{(d-1)} \cap X_d$.

**Fig. 10.** Protocol satisfying $\mathcal{F}_{\text{UPSI-del-alt}}$ in the $\mathcal{F}_{\text{UPSI-del}}$-hybrid model.
In Step 3b, by the correctness of the PSI protocol, the intersection learned by $P_0$ is $I_{X,new} =$:

$$= X_d \cap \overline{Y_d} = X_d \cap (Y_d \cup I_{Y,old} \cup \overline{D_y})$$

$$= X_d \cap (Y_d \cup I_{Y,old}) \text{ (overwhelming prob.)}$$

$$= (X_d \cap Y_d) \cup (X_d \cap I_{Y,old})$$

$$= (X_d \cap Y_d) \cup (X_d \cap (Y_d^{(d-1)} \cap X_d))$$

$$= (X_d \cap Y_d) \cup (X_d \cap Y_d^{(d-1)})$$

$$= (X_d \cap Y_d) \cup (X_d \cap Y_d^{(d-1)}) \cup (X_d \cap I_{d-1})$$

$$= (X_d \cap I_{d-1} = \emptyset \text{ because } X_d \cap X_{[d-1]} = \emptyset)$$

$$= X_d \cap (Y_d \cup Y_d^{(d-1)} \cup I_{d-1}) = X_d \cap Y_d$$

$$(Y_d^{(d-1)} \cup I_{d-1} = Y_{[d-1]} \text{ by inductive hypothesis})$$

The set computed in Step 3c is $I_{update} =$:

$$= I_{X,new} \cup I_{X,old} = (X_d \cap Y_d) \cup (X_d^{(d-1)} \cap Y_d)$$

Therefore, the new intersection computed in Step 3d is $I_d = I_{d-1} \cup I_{update} =$:

$$= (X_{[d-1]} \cap Y_{[d-1]}) \cup (X_d \cap Y_d) \cup (X_{[d-1]} \cap Y_d)$$

$$= (X_{[d-1]} \cap Y_{[d]}) \cup (X_d \cap Y_{[d]} \cap Y_{[d]})$$

In Step 4c, $P_0$ updates $X_{old} =$:

$$= (X_{old}^{(d-1)} \setminus I_{X,old}) \cup (X_d \setminus I_{update})$$

$$= (X_{old}^{(d-1)} \setminus (X_d \cap Y_d)) \cup (X_d \setminus Y_d)$$

$$= (X_{old}^{(d-1)} \setminus (X_d \cap Y_{[d]}) \cup (X_{[d-1]} \cap Y_d))$$

$$= (X_{old}^{(d-1)} \setminus Y_d) \cup (X_d \setminus Y_{[d]})$$

$$= (X_{[d-1]} \setminus Y_{[d-1]}) \cup (X_d \setminus Y_{[d]})$$

$$= (X_{[d-1]} \setminus Y_{[d]} \cup (X_d \setminus Y_{[d]})$$

To update $H_X$, notice that $I_{X,old} = X_{old}^{(d-1)} \cap Y_d \subseteq X_{old}^{(d-1)}$, thus $P_0$ can identify $H(I_{X,old})^{k_0} \approx k_1$ from $H(X_Y^{(d-1)})$. For $X_Y' = X_d \setminus I_{update}$, $P_0$ can compute $H(X_Y')^{k_0} \approx k_1$ in Step 4. Therefore, in Step 4c $P_0$ obtains $H(X_d^{(d)} = H(X_Y^{(d)}).$ Similarly we can prove these guarantees also hold for $Y_{old}^{(d)}$ and $H_Y^{(d)}$, which concludes the proof.

### C.2 Security Proof

In this section, we prove Theorem 4.1 for the security of our two-sided UPSI with addition protocol.

#### C.2.1 Security Against Corrupted $P_0$

We construct a PPT Sim$_0$ that simulates $P_0$’s view as follows. On input $(1^\lambda, X_{[D]}, f(X_{[D]}, Y_{[D]}))$, where $f(X_{[D]}, Y_{[D]}) := \{I_1, \ldots, I_D\}$ are the outputs of the ideal functionality in the $D$ days, Sim$_0$ runs the honest $P_0$ to generate its view and behaves on behalf of an honest $P_1$ with the following exceptions on each Day $d \subseteq \{D\}$:

- In Step 1a, let $I'_{X,old} := X_{[d-1]} \cap (I_d \setminus I_{d-1})$ and compute $H_I(I'_{X,old})^{k_1}$. Let $R$ be a set of $N_d - |I'_{X,old}|$ uniformly randomly sampled group elements in $G$. Send $H_I(I'_{X,old})^{k_1} \cup R$ to $P_0$ on behalf of $P_1$.
- In Step 3b, let $I'_{X,new} := X_d \cap (I_d \setminus I_{d-1})$. Receive $P_0$’s input set as the ideal functionality of $\mathcal{P}_{PSI}$ and respond to $P_0$ with $I'_{X,new}$.
- In Step 5 when $P_1$ sends $H(Y_{[d]})^{k_1} \rightarrow P_0$ (for a random $a \in \mathbb{Z}_q$), replace it with a set of $|N_d|$ uniformly randomly sampled group elements in $G$.

Finally, Sim$_0$ outputs $P_0$’s view.

We then show, via a hybrid argument, that for any $D \in \mathbb{N}^+$, any inputs $(X_{[D]}, Y_{[D]})$, $(\text{View}^\Pi_{D}(X_{[D]}, Y_{[D]}), \text{Out}^\Pi_{D}(X_{[D]}, Y_{[D]})) \Rightarrow (\text{Sim}_0(1^\lambda, X_{[D]}, f(X_{[D]}, Y_{[D]}), f(X_{[D]}, Y_{[D]})))$.

**Hyb$_0$**: $P_0$’s view and $P_1$’s output in the real protocol.

**Hyb$_1$**: Same as Hyb$_0$ but $P_1$’s output is replaced with $f(X_{[D]}, Y_{[D]})$. This is computationally indistinguishable from Hyb$_0$ because of the correctness of the protocol shown in Appendix C.1.

**Hyb$_2$**: Same as Hyb$_1$ but in Step 3b of each Day $d \subseteq \{D\}$, let $I_{X,new} := X_d \cap (I_d \setminus I_{d-1})$ and let the response from the ideal functionality of $\mathcal{P}_{PSI}$ to $P_0$ be $I'_{X,new}$. We claim that $I_{X,new} = I'_{X,new}$.

We show in Appendix C.1 that $I_{X,new} = X_d \cap Y_{[d]}$. Since $X_d \cap X_{[d-1]} = \emptyset$, we have $X_d \cap I_{d-1} = \emptyset$ and hence $(X_d \cap Y_{[d]}) \cap I_{d-1} = \emptyset$. Given that $X_d \cap Y_{[d]} \subseteq I_d$, we have $X_d \cap Y_{[d]} \subseteq I_d \setminus I_{d-1}$, thus $X_d \cap Y_{[d]} \subseteq X_d \cap (I_d \setminus I_{d-1})$, namely $I_{X,new} \subseteq I'_{X,new}$.

On the other hand, $I_d \subseteq Y_{[d]}$, hence $X_d \cap (I_d \setminus I_{d-1}) \subseteq X_d \cap I_{d-1}$, namely $I'_{X,new} \subseteq I_{X,new}$. Therefore $I_{X,new} = I'_{X,new}$.

By the correctness of the ideal functionality $\mathcal{P}_{PSI}$, the two hybrids Hyb$_1$ and Hyb$_2$ are computationally indistinguishable.
Hyb₃: Same as Hyb₂ but H is replaced with a random function. This is computationally indistinguishable to Hyb₂ because H is modeled a random oracle.

Hyb₄: Same as Hyb₃ but in Step 1a on each Day d ∈ [D], for each y ∈ Y_d \ X_{d-1}, replace H(y) with a uniformly randomly sampled group element in G. From Hyb₃ to Hyb₄, we actually replace the elements one by one via a sequence of hybrids Hyb₃,0, Hyb₃,1, ..., Hyb₃,n where Hyb₃,0 = Hyb₃ and Hyb₃,n = Hyb₄. We argue every pair of adjacent hybrids are computationally indistinguishable based on the DDH assumption.

Assume for the purpose of contradiction that there exits a PPT distinguisher A that can distinguish two adjacent hybrids Hyb₃,i and Hyb₃,i+1 where H(ŷ)ᵣ is replaced by a random group element on some Day d for some ŷ ∈ Y_d \ X_{d-1}. We construct a PPT distinguisher B to break the DDH assumption. B is given a tuple of group elements (g₁, g₂, g₃) where g₁ = gᵣ, g₂ = gᵣ for random x, y ∈ Zₚ and g₃ is either gᵣy or gᵣ for a random z ∈ Zₚ, B generates P₀’s view as in Hyb₃,i but sets k₁ := x (although x is unknown) and H(ŷ) := g₂.

In particular, whenever H(·) is computed, B samples a random r ∈ Zₚ and sets the output to be gᵣ. In Step 1a when P₁ needs to compute H(y)ᵣ, since B knows s ∈ Zₚ such that H(y) = gᵣ, it can compute H(y)ᵣ as gᵣ; when P₁ samples a random group element for H(y)ᵣ, B can do the same; for ŷ, B replaces H(ŷ)ᵣ with g₃. Since ŷ ̸∈ Xₚold and hence ŷ ̸∈ Xₚold ∩ Y_d = Iₚold, in Step 1b on Day d, thus it doesn’t affect P₀’s computation.

In Step 4b, to compute H(x)ᵣα₀k₁, since B knows α₀, k₁ and c ∈ Zₚ such that H(x) = gᵣ, it can compute H(x)ᵣα₀k₁ as g₁ᵣα₀k₁. Note that for each x in Step 4b on Day d (not considering the dummy elements), x ̸= ŷ because ŷ ̸∈ Xₚ[d-1]; for each x in Step 4b on or after Day d (not considering the dummy elements), x ̸= ŷ because x is not in the intersection. If we take the dummy elements into consideration, then x ̸= ŷ with all negligible probability, hence B doesn’t have to compute H(ŷ)ᵣα₀k₁.

If g₃ = gᵣy, then B generates P₀’s view as in Hyb₃,i; otherwise B generates P₀’s view as in Hyb₃,i+1. Since A can distinguish these two hybrids, B can break the DDH assumption. Contradiction.

Hyb₅: Same as Hyb₄ except that H is computed as normal. This is computationally indistinguishable to Hyb₅ because H is modeled as a random oracle.

We claim that P₀’s view in this hybrid is exactly Sim₀’s output. The only difference between Hyb₅ and Sim₀ is that in Step 1a on each Day d ∈ [D], H(y)ᵣ is computed honestly for all y ∈ Y_d ∩ Xₚ[d-1] in Hyb₅ while Sim₀ computes H(y)ᵣ honestly for all y ∈ Iₚold. We claim that Y_d ∩ Xₚ[d-1] = Iₚold.

Since Xₚ[d-1] ∩ Iₚ = Xₚ[d-1] \ Yₚ[d] and Xₚ[d-1] ∩ Iₚ = Xₚ[d-1] \ Yₚ[d-1], we have Iₚold = Xₚ[d-1] ∩ Iₚ \ Yₚ[d] \ Yₚ[d-1] = (Xₚ[d-1] \ Yₚ[d]) \ (Xₚ[d-1] \ Yₚ[d-1]) = Xₚ[d-1] ∩ (Yₚ[d] \ Yₚ[d-1]) = Xₚ[d-1] ∩ Yₚ[d-1] = Xₚ[d-1] \ Yₚ[d]. This concludes the proof.

C.2.2 Security Against Corrupted P₁

We construct a PPT Sim₁ that simulates P₁’s view as follows. On input (1λ, Yₚ, f(Xₚ[d], Yₚ[d])), where f(Xₚ[d], Yₚ[d]) := {I₁, ..., Iₚ} are the outputs of the ideal functionality in the D days, Sim₁ runs the honest P₁ to
generate its view and behaves on behalf of an honest $P_0$ with the following exceptions on each Day $d \in [D]$:

- In Step 2 when $P_0$ sends $H(X_d)^k_0$ to $P_1$, let $I'_{Y,old} := Y_{d-1} \cap (I_d \setminus I_{d-1})$ and compute $H(I'_{Y,old})^k_0$. Let $R$ be a set of $N_d - |Y_{old}|$ uniformly randomly sampled group elements in $G$. Send $H(I'_{Y,old})^k_0 \cup R$ to $P_1$ on behalf of $P_0$.
- In Step 3c, let $I'_{update} := I_d \setminus I_{d-1}$ and send $I'_{update}$ to $P_1$ on behalf of $P_0$.
- In Step 4a, send a set of $|N_d|$ uniformly randomly sampled group elements in $G$ to $P_1$ on behalf of $P_0$.

Finally $Sim_1$ outputs $P_1$’s view.

We show, via a hybrid argument that, for any $D \in \mathbb{N}^+$, any inputs $(X(D)|I(D))$, $(Y(D)|I(D))$, 
$\langle View^II_D(X(D)|Y(D)), Out^IV_D(X(D)|Y(D)) \rangle \approx (Sim_1(X(D)|f(X(D)|Y(D))), f(X(D)|Y(D)))$.

- $Hyb_0 : P_1$’s view and $P_0$’s output in the real protocol.
- $Hyb_1 :$ Same as $Hyb_0$ but $P_0$’s output is replaced with $f(X(D)|Y(D))$. This is computationally indistinguishable from $Hyb_0$ because of the correctness of the protocol shown in Appendix C.1.
- $Hyb_2 :$ Same as $Hyb_1$ but in Step 3c on each Day $d \in [D]$, let $I'_{update} := I_d \setminus I_{d-1}$ and send $I'_{update}$ to $P_1$ on behalf of $P_0$. This is computationally indistinguishable from $Hyb_1$ because of the correctness of the protocol shown in Appendix C.1.
- $Hyb_3 :$ Same as $Hyb_2$ but $H$ is replaced with a random function. This is computationally indistinguishable to $Hyb_2$ because $H$ is modeled a random oracle.
- $Hyb_4 :$ Same as $Hyb_3$ but in Step 2 on each Day $d \in [D]$, for each $x \in X_d \setminus Y_{d-1}$, replace $H(x)^k_0$ with a uniformly randomly sampled group elements in $G$. This hybrid is computationally indistinguishable from $Hyb_3$ based on the DDH assumption. The argument is similar to the proof of $Hyb_4 \approx Hyb_1$ in the security proof against corrupted $P_0$.
- $Hyb_5 :$ Same as $Hyb_4$ but in Step 4a on each Day $d \in [D]$, send a set of $|N_d|$ uniformly randomly sampled group elements in $G$ to $P_1$ on behalf of $P_0$. This hybrid is computationally indistinguishable from $Hyb_4$ based on the DDH assumption. The argument is similar to the proof of $Hyb_5 \approx Hyb_2$ in the security proof against corrupted $P_0$.

$Hyb_6 :$ Same as $Hyb_5$ except that $H$ is computed as normal. This is computationally indistinguishable to $Hyb_5$ because $H$ is modeled as a random oracle. Finally, we claim that $P_1$’s view in this hybrid is exactly $Sim_1$’s output. The argument is similar to the proof in $Hyb_6$ of the security proof against corrupted $P_0$. This concludes the proof.

### D. Proofs for \(II_{UPSI}\)-add-one

#### D.1 Correctness Proof

In this section, we formally prove correctness of our one-sided UPSI with addition protocol.

**Induction for \(X_{old}\).** Observe that, by induction, we can show that at the end of any Day $d$, $X_{old} = X_d \setminus I_d$ and $H_X = H_1(X_{old})^k_0k_1$. This argument is identical to the one shown in Appendix C.1.

**Day 1.** In Step 1, $P_0$ learns $\emptyset$ since $X_{old} = \emptyset$. In Step 2, both parties set $L = max L = 0$. Then, in Step 3, $P_1$ inserts the $\sigma$ elements of $Y_1$ into $D_0[0]$. $D_0[0]$ is then padded to size $4\sigma$ before the encrypted node $D_0'[0]$ is sent to $P_0$. In Step 4, $P_0$ sets $D_0[0] = D_0'[0]$. In Step 5, for each $x \in X_1$, $P_0$ computes a pair $(ct_\alpha, ct_\beta)$ for each element $ct$ in $D_0[0]$. In each pair, $ct_\beta = Enc_{pk_1}(x + \alpha - y)$, where $ct = Enc_{pk_1}(y)$. $P_1$ decrypts $ct_\beta$ in each pair and sends back $ct_\tau = Enc_{pk_0}(y \cdot (x - y))$. Now, $P_0$ can decrypt this and $Dec_{sk_0}(ct_\tau) = 0$ if and only if $x \in Y_1$ except with negligible probability (since $P_1$ also adds random dummy elements). So, $P_0$ learns $X_1 \cap Y_1$. Finally, in Step 7, $P_0$ updates $X_{old}$ and $H_X$ similarly as in the previous protocol \(II_{UPSI\text{-add-two}}\) (Figure 3).

**Day $d$.** Now, let’s analyze the protocol on any Day $d$. In Step 1, as a result of the induction-based observation above, $P_0$ learns $I_{X,old} = X_{old} \setminus Y_d$ where $X_{old} = X_{d-1} \setminus I_{d-1}$. The data structure $D$ is a binary tree of depth $max L$, where each node is of size $4\sigma$. At any $i$, we denote the $2^i$ nodes as $D_i[0], \ldots, D_i[2^i - 1]$. In Step 3, all levels $i \geq L$ remain untouched while levels $0, \ldots, L$ are completely revamped. In particular, all the elements (of $Y_{d-1}$) at levels up to $(L - 1)$ along with the new set $Y_d$ are filled into the nodes at level $L$. Each element $y$ is inserted into node $D_L[j]$ where $j$ is the leading $L$ bits of $H_2(y)$. All nodes in levels up to $(L - 1)$ are emptied. Finally, as before, these nodes are padded to size $4\sigma$, encrypted and sent to $P_0$.

**Lemma D.1.** The protocol aborts in Step 3 with negligible probability.

**Proof.** The protocol aborts if the size of any node $D_L[j]$ exceeds $4\sigma$. We show that this happens only with negligible probability. First, assuming hash function $H_2(\cdot)$ is modeled as a random oracle, any element $y \in S$
is equally likely to be placed into any node $\mathcal{D}_L[j]$ for $j \in \{0,1,\ldots,2^L - 1\}$. We now use a couple of sub-lmmas to complete the proof.

**Sub-Lemma D.2.** The number of items inserted into nodes at level $L$ is $|S| = 2^L \cdot \sigma$.

Proof. Since $L = \log_2(d)$, $d$ is of the form $d = 0 \mod 2^L$ and $d = 2^L \mod 2^L + 1$. Consider $d^* = d - 2^L$, if $d^* > 0$, then $\log_2(d^*) > L$, hence all nodes up to level $L$ are emptied and contain $\emptyset$ on Day $d^*$. Observe that an element $y$ in $P_1$’s input that is placed on a node in level $i$ is later never placed on level $i_1$ where $i_1 < i$. In particular, elements either remain at the same level or are pushed further down the tree on each day. From Day $(d^* + 1)$, the number of elements added to the tree is $\sigma \cdot (d - 1 - d^*) = \sigma \cdot (2^L - 1)$. The number of elements added on Day $d$ is $\sigma$ and hence $|S| = 2^L \cdot \sigma$. 

**Sub-Lemma D.3.** Given $N = \text{Poly}(\sigma)$ balls distributed into $\frac{N}{\sigma}$ bins, where every ball is equally likely to be placed in any bin, $\Pr[\text{size of every bin} \leq 4\sigma] \geq 1 - \text{negl}(\sigma)$.

Proof. Let $X_{i \geq k}$ be an indicator variable that the $i$-th node has at least $k$ balls. Then

$$\Pr[X_{i \geq k} = 1] \leq \binom{N}{k} \frac{1}{(N/\sigma)^k} \leq \frac{N}{k!} \leq \frac{\sigma^k}{k!} = \sigma^k \cdot \frac{1}{(4\pi)^k} \cdot (\text{Stirling’s approx.})$$

Let $k = 4\sigma$, then we have $\Pr[X_{i \geq k} = 1] \leq \frac{\sigma^k}{(4\pi)^k} \leq \frac{1}{4\pi}$. By taking a union bound we have

$$\Pr[\exists i \in N, X_{i \geq 4\sigma} = 1] \leq \frac{N}{2\pi} = \text{negl}(\sigma).$$

Combining the above two sub-lmmas, it is easy to see that no node $\mathcal{D}_L[j]$ has size more than $4\sigma$ except with negligible probability.

In Step 4, $P_0$ updates the encrypted database $\mathcal{D}$. In Step 5, for each $x \in X_d$, for each $i \in \{0,1,\ldots,\max L\}$, $P_0$ computes $H_2(x)_{1,\ldots,i}$ to identify which nodes of $\mathcal{D}$ (at each level) could possibly contain then. Then, for each such non-empty node, for each ciphertext $ct$ in it, $(ct = \text{Enc}_{pk_0}(y)$ where $y \in Y_{[d]}$ or $y$ is a random dummy element), $P_0$ computes and sends $(\text{Enc}_{pk_0}(\alpha), \text{Enc}_{pk_0}(x - y - \alpha))$. $P_1$ responds back with $\text{Enc}_{pk_0}(\gamma(x - y))$ which $P_0$ can decrypt. Observe that this is 0 if and only if $x = y$ where $y \in Y_{[d]}$ except with negligible probability (if $y$ equals a random dummy element). In this manner, $P_0$ learns whether each element $x \in X_d$ belongs to $Y_{[d]}$ and computes $I_{X,\text{new}} = X_d \cap Y_{[d]}$. Finally, in Step 7, $P_0$ updates $X_{\text{old}}$ and $H_X$ as done in the previous protocol $\Pi_{\text{UPS1-add-two}}$ (Figure 3).

### D.2 Security Proof

In this section, we prove Theorem 5.1 for the security of our one-sided UPSI with addition protocol.

#### D.2.1 Security Against Corrupted $P_0$

First, let $\text{Num1}(n)$ denote the number of 1’s in the binary representation of $n$. In other words, if $n = \sum_{i=0}^{k} b_i \cdot 2^i$, then $\text{Num1}(n) := \lceil i : b_i = 1 \rceil$. For example, $\text{Num1}(7) = 3$ and $\text{Num1}(12) = 2$. We construct a PPT $\text{Sim}_0$ that simulates $P_0$’s view as follows. On input $(1^\lambda, X_{[d]}, f(X_{[d]}, Y_{[d]}))$, where $f(X_{[d]}, Y_{[d]}):= \{(I_1, \ldots, I_D) \mid \text{the ideal functionality in the } D \text{ days, } \text{Sim}_0 \text{ runs the honest } P_0 \text{ to generate its view and behaves on behalf of an honest } P_1 \text{ with the following exceptions on each Day } d \in [D]: \}$

- In Step 1a, let $I_{X,\text{old}}^{d} := X_{[d-1]} \cap (I_d \setminus I_{d-1})$ and compute $H_1(I_{X,\text{old}}^{d})^{k_1}$. Let $R$ be a set of $(\sigma - |I_{X,\text{old}}^{d}|)$ randomly sampled group elements in $G$. Send $H_1(I_{X,\text{old}}^{d})^{k_1} \cdot R$ to $P_0$ on behalf of $P_1$.
- In Step 3c, never abort on behalf of $P_1$.
- In Step 3e, let $\mathcal{D}_L[j]$ be a set of 4$\sigma$ encryptions of 0 under $pk_1$, namely $\text{Enc}_{pk_1}(0)$. Send $\mathcal{D}_L[j]$ to $P_0$ on behalf of $P_1$.
- In Step 5(b)ii, if $x \notin I_d$, let $C_1$ be a set of $4\sigma \cdot \text{Num1}(d)$ encryptions of random elements under $pk_0$, namely $\text{Enc}_{pk_0}(r)$ for $r \sim \mathcal{D}_L[j]$; otherwise, let $C_1$ be a set containing $\text{Enc}_{pk_0}(0)$ and $(4\sigma \cdot \text{Num1}(d) - 1)$ encryptions of random elements under $pk_0$. Send $C_1$ in a randomly permuted order to $P_0$ on behalf of $P_1$.

Finally, $\text{Sim}_0$ outputs $P_0$’s view.

Via a hybrid argument, we show that for any $D \in \mathbb{N}^+$, any inputs $(X_{[d]}, Y_{[d]}))$,

$$\text{View}_{0}^{H,D}(X_{[d]}, Y_{[d]})) \approx \text{Sim}_0(1^\lambda, X_{[d]}, f(X_{[d]}, Y_{[d]}))$$

$\text{Hyb}_0 : P_0$’s view in the real protocol.

$\text{Hyb}_1 :$ Same as $\text{Hyb}_1$ but $H_1$ is replaced with a random function. This is computationally indistinguishable to $\text{Hyb}_0$ because $H_1$ is modeled a random oracle.

$\text{Hyb}_2 :$ Same as $\text{Hyb}_1$ but in Step 1a on each Day $d \in [D]$, for each $y \in Y_d \setminus X_{[d-1]}$, replace $H_1(y)^{k_1}$ with a uniformly randomly sampled group elements in $G$. From $\text{Hyb}_1$ to $\text{Hyb}_2$, we actually replace the elements one by one via a sequence of hybrids $\text{Hyb}_{1,0}, \text{Hyb}_{1,1}, \ldots, \text{Hyb}_{1,n}$ where $\text{Hyb}_{1,0} = \text{Hyb}_1$ and
Hyb_{1,n} = Hyb_2. We argue every pair of adjacent hybrids are computationally indistinguishable based on the DDH assumption.

Assume for the purpose of contradiction that there exits a PPT distinguisher A that can distinguish two adjacent hybrids Hyb_{1,i} and Hyb_{1,i+1} where $H_1(y)^{g_1}$ is replaced by a random group element on some Day d for some $\tilde{y} \in Y_d \setminus X_{d-1}$. We construct a PPT distinguisher B to break the DDH assumption. B is given a tuple of group elements $(g_1, g_2, g_3)$ where $g_1 = g^z$, $g_2 = g^y$ for random $x, y \in \mathbb{Z}_q$ and $g_3$ is either $g^{xy}$ or $g^x$ for a random $z \in \mathbb{Z}_q$. B generates $P_0$’s view as in Hyb_{1,i} but sets $k_i := x$ (although $x$ is unknown) and $H_1(\tilde{y}) := g_2$. In particular, whenever $H_1(\cdot)$ is computed, B samples a random $r \in \mathbb{Z}_q$ and sets the output to be $g^r$. In Step 1a when $P_1$ needs to compute $H_1(y)^{g_1}$, since B knows $s \in \mathbb{Z}_q$ such that $H_1(y) = g^s$, it can compute $H_1(y)^{g_1}$ as $g_1^{t_1k_0}$. When $P_1$ samples a random group element for $H_1(y)^{g_1}$, B can do the same; for $\tilde{y}$, B replaces $H_1(\tilde{y})^{g_1}$ with $g_3$. Since $\tilde{y} \notin X_{d-1}$, we have $\tilde{y} \notin X_{\text{old}}$ and hence $\tilde{y} \notin X_{\text{old}} \cap Y_d = IX_{\text{old}}$ in Step 1b on Day d, thus it doesn’t affect $P_0$’s computation.

In Step 7b, to compute $H_1(x)^{\alpha k_0 k_1}$, since B knows $\alpha, k_0, \text{ and } t \in \mathbb{Z}_q$ such that $H_1(x) = g^t$, it can compute $H_1(x)^{\alpha k_0 k_1}$ as $g_1^{t_1k_0}$. Note that for each $x$ in Step 7b before Day d (not considering the dummy elements), $x \neq \tilde{y}$ because $\tilde{y} \notin X_{d-1}$; for each $x$ in Step 7b on or after Day d (not considering the dummy elements), $x \neq \tilde{y}$ because $x$ is not in the intersection. If we take the dummy elements into consideration, then $x \neq \tilde{y}$ with all but negligible probability, hence B doesn’t have to compute $H_1(\tilde{y})^{\alpha k_0 k_1}$. If $g_3 = g^{xy}$, then B generates $P_0$’s view as in Hyb_{1,i}; otherwise B generates $P_0$’s view as in Hyb_{1,i+1}. Since A can distinguish these two hybrids, B can break the DDH assumption. Contradiction.

Hyb_2: Same as Hyb_2 but in Step 3c, $P_1$ never aborts.

By Lemma D.1, the probability that $P_1$ aborts is negligible, hence this hybrid is computationally indistinguishable from Hyb_2.

Hyb_1: Same as Hyb_3 except that in Step 5(b)ii on each day $d \in [D]$, replace each $c_t$ by a fresh encryption of $\gamma \cdot (\beta - \alpha)$ under $pk_0$. This hybrid is statistically indistinguishable from Hyb_2 by the re-randomization property of the additively homomorphic encryption scheme. In particular, the encryption $c_t$ computed from $(c_t, \beta, \gamma)$ by homomorphic operations is statistically indistinguishable from a fresh encryption of $r$ even given the secret key $sk_0$.

Hyb_3: Same as Hyb_2 except that in Step 5(b)ii on each day $d \in [D]$, if $x \notin I_d$, let $C_1$ be a set of $4 \sigma \cdot \text{Num1}(d)$ encryptions of random elements under $pk_0$, namely $\text{Enc}_{pk_0}(r)$ for $r \leftarrow \mathbb{F}_p$. Send $C_1$ in a randomly permuted order to $P_0$ on behalf of $P_1$.

First, our construction guarantees that on each day $d \in [D]$, there are exactly $\text{Num1}(d)$ levels of the tree that are non-empty, hence the size of $C_0$ is $4 \sigma \cdot \text{Num1}(d)$. If $x \notin I_d$, then for each pair $(ct_1, ct_2) \in C_0$, we know that $\beta - \alpha = x - y = 0$ with negligible probability (note that some $y$ values are randomly sampled by $P_1$, so the probability is not 0 but negligible). In case $\beta - \alpha \neq 0$, then $\gamma \cdot (\beta - \alpha)$ for a random $\gamma \leftarrow \mathbb{F}_p$ is identically distributed from a random value $r \leftarrow \mathbb{F}_p$. Therefore, this hybrid is statistically indistinguishable from Hyb_2.

Hyb_4: Same as Hyb_2 except that in Step 5(b)ii on each day $d \in [D]$, if $x \in I_d$, let $C_1$ be a set containing $\text{Enc}_{pk_0}(0)$ and $(4 \sigma \cdot \text{Num1}(d) - 1)$ encryptions of random elements under $pk_0$. Send $C_1$ in a randomly permuted order to $P_0$ on behalf of $P_1$.

If $x \in I_d$, then there exists one pair $(ct_1, ct_2) \in C_0$ such that $\beta - \alpha = 0$; for all other pairs, $\beta - \alpha = 0$ with negligible probability. For the pair such that $\beta - \alpha = 0$, $\gamma \cdot (\beta - \alpha) = 0$ for any $\gamma$. For all other pairs, in case $\beta - \alpha \neq 0$, then $\gamma \cdot (\beta - \alpha)$ for a random $\gamma \leftarrow \mathbb{F}_p$ is identically distributed from a random value $r \leftarrow \mathbb{F}_p$. Therefore, this hybrid is statistically indistinguishable from Hyb_5.

Hyb_7: Same as Hyb_6 but in Step 3e on each day $d \in [D]$, let $\overline{DL}[j]$ be a set of $4 \sigma$ encryptions of 0 under $pk_1$, namely $\text{Enc}_{pk_1}(0)$. Send $\{\overline{DL}[j]\}_{j \in \{0, 1, \ldots, 2^\ell - 1\}}$ to $P_0$ on behalf of $P_1$. This hybrid is computationally indistinguishable from Hyb_6 by the CPA security of the additively homomorphic encryption scheme.

Hyb_8: Same as Hyb_7 except that $H_1$ is computed as normal. This is computationally indistinguishable from Hyb_7 because $H_1$ is modeled as random oracles. We claim that $P_0$’s view in this hybrid is exactly $\text{Sim}_0$’s output. The only difference between Hyb_8 and $\text{Sim}_0$ is that in Step 1a on each Day $d \in [D]$, $H_1(y)^{g_1}$ is computed honestly for all $y \in Y_d \cap X_{d-1}$ in Hyb_8 while $\text{Sim}_0$ computes $H_1(y)^{g_1}$ honestly for all $y \in I_X^{\text{old}}$. We claim that $Y_d \cap X_{d-1} = I_X^{\text{old}}$. Since $X_{d-1} \cap I_d = X_{d-1} \cap Y_d$ and $X_{d-1} \cap I_{d-1} = X_{d-1} \cap Y_{d-1}$, we have $I_X^{\text{old}} = X_{d-1} \cap I_{d-1} = (X_{d-1} \cap I_d) \setminus (X_{d-1} \cap I_{d-1}) = (X_{d-1} \cap Y_d)$.
(X_{[d-1]} \cap Y_{[d-1]}) = X_{[d-1]} \cap (Y_{[d]} \setminus Y_{[d-1]}) = X_{[d-1]} \cap Y_{d}. This concludes the proof.

D.2.2 Security Against Corrupted P1

We construct a PPT Sim_1 that simulates P1’s view as follows. On input \((1^\lambda, Y_{[D]}), Sim_1 runs the honest P1 to generate its view and behaves on behalf of an honest P0 with the following exceptions on each Day \(d \in [D]::

- In Step 5(a)ii, let \(C_0\) be a set of \(4\sigma \cdot \text{Num}_1(d)\) pairs of encryptions \((ct_\alpha, ct_\beta)\), where \(ct_\alpha \leftarrow \text{Enc}_{pk_0}(0)\) and \(ct_\beta \leftarrow \text{Enc}_{pk_1}(r)\) for \(r \overset{\$}{\leftarrow} \mathbb{F}_p\). Send \(C_0\) to P1 on behalf of P0.
- In Step 7a, send a set of \(\sigma\) randomly sampled group elements in \(G\) to P1 on behalf of P0.

Finally Sim_1 outputs P1’s view.

Via a hybrid argument, we show that for any \(D \in \mathbb{N}^+\), any inputs \((X_{[D]}, Y_{[D]}), (\text{View}^{\Pi,D}_{1}(X_{[D]}, Y_{[D]}), \text{Out}^{\Pi,D}_{0}(X_{[D]}, Y_{[D]})) \overset{\$}{\approx} (\text{Sim}(1^\lambda, Y_{[D]}), f(X_{[D]}, Y_{[D]})).

Hyb_0 : P1’s view and P0’s output in the real protocol.

Hyb_1 : Same as Hyb_0 but P0’s output is replaced with \(f(X_{[D]}, Y_{[D]}). This is computationally indistinguishable from Hyb_0 because of the correctness of the protocol shown in Appendix D.1.

Hyb_2 : Same as Hyb_1 but H1 is replaced with a random function. This is computationally indistinguishable to Hyb_1 because H1 is modeled a random oracle.

Hyb_3 : Same as Hyb_2 but in Step 7a on each Day \(d \in [D]\), send a set of \(\sigma\) randomly sampled group elements in \(G\) to P1 on behalf of P0. This hybrid is computationally indistinguishable from Hyb_2 based on the DDH assumption. The argument is similar to the proof of Hyb_1 \(\overset{\$}{\approx} Hyb_2\) in the security proof against corrupted P0.

Hyb_4 : Same as Hyb_3 except that in Step 5(a)ii on each day \(d \in [D]\), replace each \(ct_\beta\) by a fresh encryption of \((x + \alpha - y)\) under pk_1. This hybrid is statistically indistinguishable from Hyb_3 by the re-randomization property of the additively homomorphic encryption scheme.

Hyb_5 : Same as Hyb_4 except that in Step 5(a)ii on each day \(d \in [D]\), replace each \(ct_\alpha\) by a fresh encryption of 0 under pk_0. This hybrid is computationally indistinguishable from Hyb_4 by the CPA security of the additively homomorphic encryption scheme.

Hyb_6 : Same as Hyb_5 except that in Step 5(a)ii on each day \(d \in [D]\), replace each \(ct_\beta\) by a fresh encryption of \(r\) for a random \(r \overset{\$}{\leftarrow} \mathbb{F}_p\) under pk_1. We know that \((x + \alpha - y)\) is identically distributed from a random value \(r \overset{\$}{\leftarrow} \mathbb{F}_p\). Hence this hybrid is identically indistinguishable from Hyb_5.

Our construction guarantees that on each day \(d \in [D]\), there are exactly \(\text{Num}_1(d)\) levels of the tree that are non-empty, hence the size of \(C_0\) is \(4\sigma \cdot \text{Num}_1(d)\). Thus, in this hybrid, \(C_0\) contains \(4\sigma \cdot \text{Num}_1(d)\) pairs of encryptions \((ct_\alpha, ct_\beta)\), where \(ct_\alpha \leftarrow \text{Enc}_{pk_0}(0)\) and \(ct_\beta \leftarrow \text{Enc}_{pk_1}(r)\) for \(r \overset{\$}{\leftarrow} \mathbb{F}_p\).

Hyb_7 : Same as Hyb_6 except that H1 is computed as normal. This is computationally indistinguishable to Hyb_6 because H1 is modeled as a random oracle. P1’s view in this hybrid is exactly Sim_1’s output. This concludes the proof.

E Extension of \(\Pi_{UPSI-add-one}\)

In this section, we extend our one-sided UPSI with addition protocol \(\Pi_{UPSI-add-one}\) (in Figure 5) to the general setting when the number of elements added by both parties on any day \(N_d \neq \sigma\). For simplicity, let’s assume \(N_d\) is a multiple of \(\sigma\) (we can always pad with dummy elements to make it a multiple of \(\sigma\)).6 The high level idea is to split the input into \(N_d/\sigma\) batches of length \(\sigma\) and essentially run the basic protocol over multiple days, with \(\sigma\) elements as input on each day. We use a separate counter \(d^*\) to track the ‘day number’ of the basic protocol. We provide more details below.

Let \(X_d = \{X_{d^*}^1, X_{d^*}^2, \ldots, X_{d^*}^d\}\), \(Y_d = \{Y_{d^*}^1, Y_{d^*}^2, \ldots, Y_{d^*}^d\}\) be the two input sets split into \(N_d/\sigma\) batches of length \(\sigma\) each. First, run the basic protocol on a fresh day \((d^* + 1)\) for the basic protocol) with inputs \(X_{d^*}\) and \(Y_{d^*}\). Let’s call this sub-day \(d^*\) to indicate that this is the counter for the underlying basic protocol. Then, run the basic protocol on sub-day \((d^* + 1)\) with inputs \(X_{d^*+1}\) and \(Y_{d^*+1}\). Repeat this till the basic protocol is run on sub-day \((d^* + N_d/\sigma - 1)\) using inputs \(X_{d^*+N_d/\sigma-1}\) and \(Y_{d^*+N_d/\sigma-1}\). Finally, before moving to day \((d + 1)\) where both parties have fresh inputs, we update \(d^* = (d^* + N_d/\sigma)\). (If \(N_d = \sigma\), we would have \(d^* = d^* + 1\) as in the basic protocol). While this is the high level approach, unfortunately, the protocol does not quite work. Briefly, running the basic protocol on \(N_d/\sigma\) sub-days

\[ \text{We note that } P_0\text{'s input size actually need not be padded to a multiple of } \sigma \text{ because she can make queries for each element } x \in X_d \text{ independently.} \]
leaks the intermediate output each time and this is undesirable (and not leaked in the ideal world). Instead, the idea is to run the steps where the “actual intersection” is computed only once across these many batches.

In more detail, Step 1 is not run on each sub-day from $d^*$ to $(d^* + N_d/\sigma - 1)$ – instead, we run the step only on day $d^*$ with $P_1$’s input as $Y_d$ (and not only $Y_d^{\star}$) to allow $P_0$ to learn $X_{\text{old}} \cap Y_d$. Observe that Step 1 does not require either party’s set to be of size $\sigma$. Next, Step 5 is also not run on each sub-day – we run steps Step 3 and Step 4 on each sub-day to update the database and finally, only on day $(d^* + N_d/\sigma - 1)$, execute Step 5 (with $P_0$ using entire input set $X_d$) to allow $P_0$ to compute $X_d \cap Y_{[d]}$. Further, as an optimization, even in Step 3, $P_1$ need not send the encrypted database $\{\tilde{D}'_L[j]\}_{j \in \{0,1,\ldots,2^L-1\}}$ on each sub-day. Consider two sub-days $d_a, d_b$ with $d_a < d_b$ and $L = \text{LS1}(d_a) = \text{LS1}(d_b)$. Now, on sub-day $d_b$, all the updates to $\{\tilde{D}'_L[j]\}$ overwrite the updates $\{\tilde{D}'_L[j]\}$ made to the database on sub-day $d_a$. In particular, the elements written to the database on sub-day $d_a$ are pushed a level down the tree before the updates on sub-day $d_b$ are recorded on level $L$. Building on this idea, let $\text{maxL}_d$ be the maximum value of $L$ over the sub-days $d^*, d^* + 1, \ldots, (d^* + N_d/\sigma - 1)$. At the end of sub-day $(d^* + N_d/\sigma - 1)$, $P_0$ sends $\{\tilde{D}'_L[j]\}_{j \in \{0,1,\ldots,2^L-1\}}$ for all $L \in \{0, \ldots, \text{maxL}_d\}$ where $\{\tilde{D}'_L[j]\} \neq \emptyset$. Naturally, this reflects only the “latest state” of any level in the tree. Finally, execute Step 7 only on sub-day $(d^* + N_d/\sigma - 1)$.

We describe the whole protocol in Figure 11 for completeness.

**Efficiency for Extended Protocol.** Finally, we discuss the efficiency of our extended protocol. Intuitively, since we run $\lfloor N_d/\sigma \rfloor$ instances of the basic case (where inputs are of size $\sigma$), an upper bound on the communication and computation cost on any day is $\lfloor N_d/\sigma \rfloor$ times that of the basic case’s cost. We can in fact do better than just repeating the protocol so many times but we ignore that for the sake of simplifying the analysis and provide a relatively loose upper bound. Given the efficiency analysis in Section 5.4 for the basic case, we can conclude the amortized communication and computation cost (for each party) in the extended protocol is $O(\lfloor N_d/\sigma \rfloor \cdot \sigma \cdot \log N)$. This grows only logarithmically with the total number of elements so far.

**F Instantiations of $F_{\text{SSPSI}}$**

In this section, we describe how the PSI protocols of Kolesnikov et al. [KKRT16], Pinkas et al. [PRTY19], Chase and Miao [CM20] immediately satisfy Definition 6.1. Each of these protocols is based on semi-honest OT and correlation robust hash functions. At a high level, in each of these protocols, the sender’s input is used only in the last step to compute the oblivious pseudorandom function (OPRF) values before they are sent to the receiver. As a result, this can be done in a streaming manner so long as the maximum number of values to be computed upon are known apriori to set up the OPRF key. We now provide more details.

**Protocol Structure.** All the three protocols have the following high level structure. Consider a sender $S$ with input set $X$ and receiver $R$ with input set $Y$. In the first phase, both parties run an interactive protocol to jointly generate a key $K$ for an OPRF and evaluate $R$’s input on this OPRF obliviously. In a bit more detail, at the end of this interactive protocol, $S$ learns the key $K$ (and nothing about $R$’s input) and $R$ learns the evaluations $\{\text{OPRF}(K, y)\}_{y \in Y}$ (and nothing about the key $K$). For each $z = \text{OPRF}(K, y)$, the receiver also learns that this is the evaluation of its corresponding input element $y$ (that is, the outputs aren’t permuted). In the protocol of Kolesnikov et al. [KKRT16], $R$’s inputs are first separated into various buckets via Cuckoo hashing [PR04] and a separate instance of this OPRF protocol is run for each bucket - the sender learns one OPRF key $K_i$ for each bucket and $R$ learns $\text{OPRF}(K_i, y)$ for the element $y$ that falls into this bucket. In the protocols of [PRTY19] and [CM20], a multi-point OPRF is set up where $S$ learns a single key $K$ and $R$ learns the evaluation of all its points - $\{\text{OPRF}(K, y)\}_{y \in Y}$. Our key observation is that, crucially, so far, the sender does not need to know its input. Instead, $S$ only needs to know the size (or an upper bound) of its input set to allow the key $K$ to be chosen.

In the next phase, $S$ sends evaluations of the OPRF on its input elements to $R$. That is, $S$, in possession of key $K$ locally computes and sends $\{\text{OPRF}(K, x)\}_{x \in X}$ (in the case of [KKRT16], $S$ evaluates $\text{OPRF}(K_i, x)$ for every possible $x \in X$ that can fall into bucket $i$, for each $i$). The receiver can then compare $\{\text{OPRF}(K, x)\}_{x \in X}$ with $\{\text{OPRF}(K, y)\}_{y \in Y}$ to compute the intersection. The security guarantee of the OPRF is that for any $x \in X \setminus I$, $\text{OPRF}(K, x)$ appears pseudorandom to $R$ and hence leaks no information about the element $x$. 

Initialization: Same as Figure 5. Also, both parties set $d^* := 1$.

**Day d:** $P_0$ inputs a set $X_d$ of size $N_d$; $P_1$ inputs a set $Y_d$ of size $N_d$.

Let $X_d = \{X'_{d,0}, X'_{d,1}, \ldots, X'_{d,X_d/N_d} \}$ and $Y_d = \{Y'_{d,0}, Y'_{d,1}, \ldots, Y'_{d,Y_d/N_d} \}$ where each $X'_i$, $Y'_i$ is of size $\sigma$.

1. $P_0$ learns $I_{X,old} = X_{old} \cap Y_d$:
   (a) $P_1$ computes $H_1(Y_d)^{k_1}$ and sends to $P_0$.
   (b) On receiving $H_1(Y_d)^{k_1}$, $P_0$ raises each element to the power $k_0$ to obtain $H_1(Y_d)^{k_0k_1}$ and compares with $H_X$ (which equals to $H_1(X_{old})^{k_0k_1}$) to learn $I_{X,old} = X_{old} \cap Y_d$.

2. Both parties set $\text{max}L_d = 0$.

3. For each $i \in \{d^*, d^* + 1, \ldots, (d^* + N_d/\sigma - 1) \}$, do the following:
   (a) Both parties set $L := L_{SI}(t)$, $\text{max}L := \text{max}(L, \text{max}L)$, $\text{max}L_d = \text{max}(L, \text{max}L_d)$.
   (b) $P_1$ updates $D$ by doing the following:
      i. Let $S := \left( \bigcup_{i=0}^{L-1} \bigcup_{j=0}^{2^i-1} D[i,j] \right) \cup Y'_i$.
      ii. For each $i \in \{0, 1, \ldots, L \}$ and for each $j \in \{0, 1, 2^i - 1 \}$, set $D[i,j] := \emptyset$.
      iii. For each element $x \in S$, let $j := H_2(y[i], L)$ and add $y$ into the node $D[i,j]$. If the size of $D[i,j]$ exceeds $4\sigma$, then abort.
      iv. For each $i \in \{0, 1, 2^L - 1 \}$, construct a node $D'_L[j]$ of size $4\sigma$ by padding $D_L[j]$ with dummy random elements.
      Compute $\overline{D}_L'[j] \leftarrow \text{Enc}_{\sigma_1}(D'_L[j])$.

Finally, for each $L \in \{0, \ldots, \text{max}L_d \}$, $P_1$ sends $\{\overline{D}_L'[j] \}_{j \in \{0, 1, \ldots, 2^L - 1 \}}$ to $P_0$ if $\{\overline{D}_L'[j] \} \neq \emptyset$.

4. $P_0$ updates $\overline{D}$ by doing the following:
   For each $L \in \{0, \ldots, \text{max}L_d \}$, $j \in \{0, 1, \ldots, 2^L - 1 \}$: if $P_0$ received $\overline{D}_L'[j]$ from $P_1$ in the above step, set $\overline{D}_L[j] := \overline{D}_L'[j]$; else, set $\overline{D}_L[j] := \emptyset$.

5. $P_0$ learns $I_{X,\text{new}} = X_d \cap Y_d$:
   $P_0$ first sets $I_{X,\text{new}} := \emptyset$. Then for each $x \in X_d$:
   (a) $P_0$ does the following:
      i. Set $C_0 := \emptyset$.
      ii. For each $i \in \{0, \ldots, \text{max}L \}$, set $j := H_2(x[i], L)$; if $\overline{D}_L[j] \neq \emptyset$, then for each $ct \in \overline{D}_L[j]$:
         Sample $\alpha \leftarrow \mathbb{F}_p$, compute $ct_\alpha \leftarrow \text{Enc}_{\sigma_1}(\alpha)$, $ct_\beta \leftarrow \text{Enc}_{\sigma_1}(x + \alpha) \oplus ct$, and add $(ct_\alpha, ct_\beta)$ to $C_0$.
      iii. Send $C_0$ to $P_1$.
   (b) $P_1$ does the following:
      i. Set $C_1 := \emptyset$.
      ii. For each pair $(ct_\alpha, ct_\beta) \in C_0$, sample $\gamma \leftarrow \mathbb{F}_p$, compute $\beta \leftarrow \text{Dec}_{\sigma_1}(ct_\beta)$ and $ct_\gamma \leftarrow \gamma \oplus (\text{Dec}_{\sigma_1}(\beta) \oplus \alpha)$ and add $ct_\gamma$ to $C_1$.
      iii. Send $C_1$ in a randomly permuted order to $P_0$.
   (c) $P_0$ does the following:
      For each $ct_\gamma \in C_1$, compute $r \leftarrow \text{Dec}_{\sigma_1}(ct_r)$ and add $x$ to the set $I_{X,\text{new}}$ if $r = 0$.

6. $P_0$ computes and outputs $I_d := I_{d-1} \cup I_{X,old} \cup I_{X,\text{new}}$.

7. $P_0$ updates $X_{old}$ and $H_X$ as in Figure 5.

8. Finally, both parties update $d^* := d^* + N_d/\sigma$.

**Fig. 11.** One-sided UPSI with addition protocol $\Pi_{UPSI\text{-add-one}}$ when $N_d \neq \sigma$.

In sender-streaming PSI, observe that both parties can run the first phase with the sender only providing an upper bound of the number of elements it will eventually stream. Then, for any stream $X_i$ (including the initial one $X_0$), $S$ can compute and send $\{$OPRF$(K, x)\}_{x \in X_i}$ and $R$ can then immediately learn $(X_i \cap Y)$. The security of this protocol immediately follows from that of the underlying PSI protocol so long as the number of elements streamed by the sender is less than the upper bound that was set. Thus, we obtain Lemma 6.2.

**Efficiency.** We briefly analyze the efficiency of realizing $F_{\text{PSI}}$ using each of these three instantiations [KKRT16, PRTY19, CM20]. In the initialization phase, to set up the OPRF key (and evaluate $R$'s input), the computational complexity (per party) is $O(|Y| \cdot \lambda)$ and the communication complexity (from $R$ to $S$) is $O(|Y| \cdot \lambda)$ bits, where $\lambda$ is the security parameter. Note that the communication also grows with Max, but the growth is dominated by $O(|Y| \cdot \lambda)$ for any polynomially large $\text{Max}$, so we omit it here. Then for each stream $X_i$ (including $X_0$), $S$ evaluates and sends the OPRF values on $X_i$, where the computational complexity (of $S$) is $O(|X_i| \cdot \lambda)$ and the communication complexity (from $S$ to $R$) is $O(|X_i| \cdot \sigma)$, where $\sigma$ is the statistical security parameter.
G Proofs for \( \Pi_{\text{UPSI-del}} \)

G.1 Correctness Proof

We prove by induction the guarantee that \( I_d = ((X[d] \setminus X[d-t]) \cap Y_d) \cup ((Y[d] \setminus Y[d-t]) \cap X_d) \) in the UPSI with weak deletion protocol.

It is easy to observe that this guarantee holds on Day 1 since, by the correctness of the initialization phase of \( F_{\text{SSPSI}} \) and \( F_{\text{SSPSI}}^{\Pi_1} \), both parties learn the intersection \((X_1 \cap Y_1)\).

Consider Day \( d \) with new input sets \( X_d \) and \( Y_d \) respectively. In Step 1, for each \( j > 0 \), by the correctness of the \( j^{th} \) stream of \( F_{\text{SSPSI}}^{\Pi_1} \), \( P_0 \) indeed learns \( X_j \cap Y_d \).

Thus, \( I_{0,\alpha} = \bigcup_{i=(d-t+1)}^{d-1} (X_i \cap Y_d) = (X[d-1] \setminus X[d-t]) \cap Y_d \).

Similarly, in Step 2, for each \( j > 0 \), \( P_1 \) indeed learns \( Y_j \cap X_d \). Thus, \( I_{1,\alpha} = (Y[d-1] \setminus Y[d-t]) \cap X_d \).

In Step 3, by the correctness of the initialization phase of \( F_{\text{SSPSI}}^{\Pi_1} \), \( P_0 \) learns \( I_{0,\beta} =: (X[d] \cap B) = (X_d \cap Y_d) \cup (\bigcup_{i=d-t+1}^{d-1} Y_i \cap X_d \cap X_d) \cup (X_d \cap \overline{Y}) \).

(overwhelming prob. as random \( \overline{Y} \))

\( = (X_d \cap (Y[d] \setminus Y[d-t])) \).

Similarly, in Step 4, \( I_{1,\beta} = Y_d \cap (X[d] \setminus X[d-t]) \).

Finally, \( P_0 \) outputs \( I_d = I_{0,\alpha} \cup I_{0,\beta} =: (X[d-1] \setminus X[d-t]) \cap Y_d \cup (X[d] \cap (Y[d] \setminus Y[d-t])) \).

G.2 Security Proof

In this section, we prove Theorem 6.3 for the security of our two-sided UPSI with weak deletion protocol.

G.2.1 Security Against Corrupted \( P_0 \)

Consider an adversary \( A \) that corrupts party \( P_0 \). We construct a PPT Sim0 that, on input \( (1^\lambda, X[D], N[D], f(X[D], Y[D])) \), where \( f(X[D], Y[D]) := \{I_1, \ldots, I_d\} \) are the outputs of the ideal functionality in the \( D \) days, interacts with adversary \( A \) as follows and outputs \( A \)'s view.

Day 1: On behalf of functionality \( F_{\text{SSPSI}}^{\Pi_1} \), send output \( I_1 = f(X[1], Y[1]) \) to \( A \).

Day \( d \):

1. \( I_{0,\alpha} = \bigcup_{i=(d-t+1)}^{d-1} (X_j \cap Y_d) \): For each \( j > 0 \), on behalf of functionality \( F_{\text{SSPSI}}^{\Pi_1} \), send \( (X_j \cap (I_d \setminus I_{d-t})) \) to \( A \). Observe that this is equal to \( X_j \cap Y_d \) since \( X_i \)'s are mutually disjoint set.

2. \( I_{0,\beta} = (X_d \cap (\bigcup_{j=d-t+1}^{d} Y_j)) \): Observe that \( (X_d \cap I_d) = (X_d \cap (Y[d] \setminus Y[d-t])) \). Thus, on behalf of functionality \( F_{\text{SSPSI}}^{\Pi_1} \), send \( (X_d \cap I_d) \) to \( A \).

We now show that the above simulation strategy against a corrupt \( P_0 \) is successful via a series of hybrid arguments where \( \text{Hyb}_0 \) corresponds to the real world and \( \text{Hyb}_3 \) corresponds to the ideal world execution.

1. \( \text{Hyb}_0 \): This corresponds to the real world execution where \( A \) interacts with a simulator \( \text{SimHyb} \) that plays the role of honest \( P_1 \).

2. \( \text{Hyb}_1 \): In this hybrid, on Day 1, \( \text{SimHyb} \) sends output \( I_1 \) to \( A \) on behalf of the ideal functionality \( F_{\text{SSPSI}}^{\Pi_1} \). This is part of \( \text{Sim0} \)'s input on Day 1 of the protocol.

3. \( \text{Hyb}_2 \): In this hybrid, on any Day \( d \), to compute the term \( I_{0,\alpha} \), for each \( j \in \{d-t+1, \ldots, d-1\} \), \( j > 0 \), on behalf of functionality \( F_{\text{SSPSI}}^{\Pi_1} \), \( \text{SimHyb} \) sends \( (X_j \cap (I_d \setminus I_{d-t})) \) to \( A \), where \( X_j, I_d, I_{d-t} \) are part of \( \text{Sim0} \)'s input.

4. \( \text{Hyb}_3 \): In this hybrid, on any Day \( d \), to compute the term \( I_{0,\beta} \), on behalf of functionality \( F_{\text{SSPSI}}^{\Pi_1} \), \( \text{SimHyb} \) sends \( (X_d \cap I_d) \) to \( A \).

We now show that every pair of successive hybrids is computationally indistinguishable.

Lemma G.1. \( \text{Hyb}_0 \) is identically distributed to \( \text{Hyb}_1 \).

Proof. In both hybrids, \( A \) sends input \( X_1 \) to \( F_{\text{SSPSI}}^{\Pi_1} \). In \( \text{Hyb}_0 \), honest \( P_1 \) sends input \( (Y_1, \text{Max}_1) \) to \( F_{\text{SSPSI}}^{\Pi_1} \). By the correctness of \( F_{\text{SSPSI}} \), \( A \) receives output \((X_1 \cap Y_1)\). In \( \text{Hyb}_1 \), by the definition of functionality \( F_{\text{UPSI-del}} \), the value \( I_1 = f(X[1], Y[1]) \) sent by \( \text{SimHyb} \) on behalf of \( F_{\text{SSPSI}}^{\Pi_1} \) is equal to \((X_1 \cap Y_1)\). Since there is no other difference between the two hybrids, they are identical. \( \square \)
Lemma G.2. \( \text{Hyb}_1 \) is identically distributed to \( \text{Hyb}_2 \).

Proof. In \( \text{Hyb}_1 \), to compute the term \( I_{0,\alpha} \), for each \( j \in \{d-t+1, \ldots, d-1\} \), \( j > 0 \), honest \( P_1 \) sends streamed input \( Y_d \) to \( F_{SSPSI}^{P_1,j} \) and \( A \) gets output \((X_j \cap Y_d)\) by the correctness of functionality \( F_{SSPSI} \). In \( \text{Hyb}_2 \), for each \( j \), SimHyb sends \((X_j \cap (I_d \setminus I_{d-1}))\) to \( A \) on behalf of \( F_{SSPSI}^{P_1,j} \). By the definition of functionality \( F_{UPSI-de} \) and the fact that each party’s input set is mutually disjoint on each day, \((X_j \cap (I_d \setminus I_{d-1}))\) is indeed equal to \((X_j \cap Y_d)\).

Lemma G.3. \( \text{Hyb}_2 \) is statistically indistinguishable from \( \text{Hyb}_3 \).

Proof. In both hybrids, to compute the term \( I_{0,\beta} \), \( A \) sends input \( X_d \) to \( F_{SSPSI}^{P_1,d} \). In \( \text{Hyb}_2 \), honest \( P_1 \) sends initial input \((B, \text{Max}_d)\) where \( B = Y_d \cup (\bigcup_{j=d-t+1}^{d-1} (Y_j \cap X_d) \cup \hat{D}_Y) \) where \( \hat{D}_Y \) consists of dummy random elements. By the correctness of functionality \( F_{SSPSI} \), except with negligible probability, \( A \) gets output \( X_d \cap (Y_d \setminus Y_{[d-t+1]}) \) - note that the only scenario when this is not the output is if \( \hat{D}_Y \cap X_d \neq \emptyset \). In this case, the output has more elements but since \( \hat{D}_Y \) consists of dummy random elements, this occurs only with negligible probability.

In \( \text{Hyb}_3 \), SimHyb sends \((X_d \cap I_d)\) to \( A \) on behalf of \( F_{SSPSI} \). By the definition of functionality \( F_{UPSI-de} \), observe that \((X_d \cap I_d)\) is indeed equal to \( X_d \cap (Y_d \setminus Y_{[d-t-1]}) \). Since there is no other difference between the two hybrids, they are statistically indistinguishable.

G.2.2 Security Against Corrupted \( P_1 \)

Since the protocol is symmetric, the proof is identical to the above case where \( P_0 \) was corrupt.
